as-prepared MoS_2 QDs exhibited the highest electrocatalytic activity for the generation of hydrogen evolution reactions (HER) because of the high specific surface area, excellent electrical conductivity, and abundant active edge sites. Caigas et al. (2018) used pulsed LA technology for doping of WS_2 quantum dots with diethylenetriamine (DETA). As-prepared DETA-doped 2H-WS_2 QDs were found to have an average size of $\sim$6 nm. It was interesting to note that PL in WS_2 QDs was enhanced by 74-fold on DETA doping. A dopant-dependent negative photoconductivity was also observed for WS_2 QDs, which may be due to light-induced desorbing of water (oxygen) molecules on the surface.

Ou et al. (2018) reported an ultrafast LA method for the synthesis of MoS_2 quantum dots. It was also revealed that as-prepared QDs exhibited stability and high activity in the electrocatalytic HER. This was attributed to defective structure, very large surface area, high conductivity, and abundance of active sites. As-prepared QDs could be used in sensing, optics, conversion technologies, and energy storage. Sunitha et al. (2018) prepared MoS_2 QDs by pulsed LA from bulk MoS_2 pellets in deionized water. A hexagonal structure of as-prepared MoS_2 pellet was confirmed by XRD and Raman spectra. The mean particle size of these MoS_2 QDs was found to be in the range of 2−30 nm. Kuriakose et al. (2019) synthesized Au-CdS core−shell structure via a laser-assisted method. A gold core was obtained with 8.8 nm average particle size, which was surrounded by a shell coating of CdS (5.8 nm; average diameter). They observed that the rate of photodegradation of methylene blue was more in the presence of Au/CdS core shell as compared to only CdS.

Nguyen et al. (2019a) developed a simple and green route to synthesize highly photoluminescent MoS_2/WS_2 QDs using LA (femtosecond) of raw MoS_2/WS_2 powders. It was reported that as-prepared MoS_2/WS_2 QDs exhibited excellent photostability and intense PL in the blue region with a PLQY of 22.5%. An intense fluorescent emission was attributed to the presence of abundant surface functional groups, such as C−O, CO, and C−N, which can introduce new surface-state emission centers efficiently. Xu et al. (2019) reported a facile method for the synthesis of molybdenum disulfide QDs and tungsten disulfide QDs using LA (femtosecond) and sonication-assisted liquid exfoliation. Average size of these quantum dots was determined to be 3.7 and 2.1 nm, respectively. These MoS_2 and WS_2 QDs exhibited bright blue−green luminescence in the presence of UV irradiation, which may be due to the abundance of functional groups on their surfaces.

An et al. (2020) attempted different methods to produce MoS_2 QDs, such as substrate growth, exfoliation, and colloidal synthesis. MoS_2 QDs with a size of 10 nm were obtained. The resistive switching devices were fabricated using as-prepared MoS_2 QD samples. These devices exhibited a stable unipolar resistive switching behavior without any electroforming process. Soheyli et al. (2020) prepared multicomponent In-based QDs in aqueous phase. They could also tune absorption and PL emission spectra of these

QDs by changing composition of QDs such as Ag-In-S/ZnS, Zn-Ag-In-S/ZnS, and Cu-Ag-In-S/ZnS core/shell QDs. They could produce intense emission by colloidal QDs with amber, green, and red colors. According to them, there is a potential in AgInS-based/ZnS QDs to be used as theranostic agents for treatment and imaging of cancer.

Zhao et al. (2020) designed and fabricated near-infrared fluorescence. When these amorphous Ag_2S QDs were doped by Cu, then a redshift of nontoxic amorphous $Ag_{2-x}Cu_xS$ quantum dots was observed, which improved photothermal conversion efficiency to 44.0%. This may be attributed to the generation of intragap states introduced on Cu doping. It was also revealed that as-prepared amorphous $Ag_{2-x}Cu_xS$ QDs exhibited high long-term biocompatibility also. The MoS_2 quantum dots were synthesized by Pradhan et al. (2021) via pulsed LA assisted photoexfoliation of solid MoS_2 target in distilled water. The average sizes of these MoS_2 quantum dots were $\sim$4, 2.9, and 6.1 nm, when ablation durations were 5, 10, and 20 min, respectively at a fixed laser energy of 40 mJ. The quantum dots resulted in luminescence in the visible region. The as-synthesized MoS_2 quantum dots (colloidal solution) in distilled water exhibited a redshift from excitation wavelength-dependent luminescence, which shifted to longer wavelength by varying excitation wavelength from 290 to 390 nm. It was observed that MoS_2 quantum dots exhibited higher rate of generating hydrogen.

4.3.4 Metal selenides

Singh et al. (2010) could achieve selenium QDs (with 2.74 $\pm$ 2.32 nm diameter) on laser irradiation for 15 min. It was reported that almost 3.75 $\pm$ 0.15 nm size is the quantum confinement limit for QDs of selenium. It was observed that surface defect density of these QDs increases, and defect/electron trap level energy decreases with the time of laser irradiation. CdSe quantum dots were prepared by Horoz et al. (2012) by LA in water. It was reported that as-synthesized CdSe QDs (wurtzite crystal structure) were having average particle size of around 5 nm. These QDs can be attached to ZnO nanowires, so that they can find applications in QD-sensitized nanowire solar cells.

Yang et al. (2017) proposed a femtosecond LA in microfluidics approach, which is free from toxic chemicals. ZnSe quantum dots were found to be in the range of 4−6 nm using hyperbranched polyethyleneimine as functional and structural coated layer; both. An aqueous nanosized micelles consisting of these quantum dots exhibited emission of bright green light. These quantum dots have a great potential for biomedical imaging. Je et al. (2018) synthesized PbSe QDs via PLIL method. It was found that as-prepared sample in PVP solution resulted in the formation of PbSe QDs rock salt crystalline with size of about 6.83 nm. The particle size of PbSe QDs was found to be dependent on wavelength and power of the laser as well as type and concentration of the surfactants.

Balati et al. (2019) synthesized $MoSe_2$ nanosheets, inorganic fullerene-like (IF) $MoSe_2$ and MoO_3 quantum dots using PLAL method. It was then followed by a microwave treatment of bulk-$MoSe_2$ powders. It was interesting to note that two successive microwave steps changed orientation of $MoSe_2$ crystal from horizontal to vertical.

AlGhamdi et al. (2020) reported dye sensitized solar cells, where a TiO_2 photoanode was cosensitized by organic dye N719 and CdSe quantum dots. The photovoltaic performance of this cell (cosensitized with an optimum concentration of CdSe-QDs) was found to be better than that cell, where photoanode was sensitized by N719 dye. It was observed that photovoltaic conversion efficiency of this cell cosensitized by CdSe-QDs (1 mg/15 mL of ethanol) and N719 dye was 7.09%, which was almost 37% rise in photovoltaic efficiency, as compared to the cell, which is sensitized by the N719 dye only.

Omran et al. (2021) prepared cadmium selenide quantum dots using clean-LA in ethanol. It was reported that as-prepared CdSe QDs has a cubic crystal structure with average particle size of 4 nm. These QDs can find application in dye-sensitized solar cells with higher conversion efficiency.

4.4 Nonmetal-based quantum dots

4.4.1 Carbon-based quantum dots

Yu et al. (2014) prepared CQDs/TiO_2 nanosheet (TNS) composites via a simple low-temperature process. It was indicated that TNS were combined well with CQDs via surface carbon−oxygen groups. The photocatalytic activity of this composite was investigated for degradation of rhodamine B in presence of visible light, which was more as compared with CQDs/P25 composites and TNS only.

Nguyen et al. (2016) prepared carbon nanodots (C-dots) using femtosecond LA of graphite powders. Here, they used polyethylene glycol (PEG200N) solution and different concentrations of graphite. The photoluminescent quantum yield of as-prepared C-dots was significantly increased on decreasing the graphite concentration, reaching up to 21%. These C-dots could be used as an efficient fluorescent nanosensor probes for selective and sensitive detection of Fe^{3+} ions because of their high PL.

Synthesis of fluorescent carbon dots-like nanostructures (CNDs) was reported by Reyes et al. (2016) via LA of a carbon solid target in liquid. It was reported that size of close-spherical amorphous CNDs ranged between 5 and 20 nm. An efficient light emission due to excitation at 3.54 eV was observed with the PL intensity, which was centered at 3.23 eV. It was possible to tune the emission wavelength of the CNDs from the near-UV to the green region by adjusting ablation time as well as by modification of ablation and excitation laser wavelength.

Nguyen et al. (2019b) prepared C-dots with broad emissions via femtosecond LA in ethylenediamine solution. The C-dots were found suitable for a broad range of applications, including optical down-conversion devices, bioimaging, and biosensors by selecting different excitation wavelengths without changing their structures. As-prepared C-dots exhibited broad PL from blue to green regions. It was reported that abundant of functional groups created were on the surface of C-dots such as C-N, C-H, and C-O.

Ren et al. (2019) fabricated N-doped micropore CQDs (NM-CQDs) from biomass using a pulsed LA method with a high quantum yield and dual-wavelength PL emission. They observed two coexisting indigo−blue PL emissions in these QODs. The fluorescence lifetime and quantum yield of as-obtained NM-CQDs were as high as 6.56 ns and 32.4%, respectively. It was reported that these NM-CQDs are quite suitable for cellular staining images due to stable and strong PL emission. This high fluorescence of NM-CQDs can find a great potential in engineering and biomedical imaging.

Cui et al. (2020) fabricated CQDs through ultrafast dual beam pulsed LA using low-cost carbon cloth. As-prepared CQDs were homogeneous and the quantum yield of emission was around 35.4%. These QDs exhibited a good stability and excellent performance for anti-jamming, so that these were found suitable for cell bioimaging.

It is difficult to introduce S into the carbon framework of GQDs as its size is much larger than that of C atoms, as-compared to B and N. Kang et al. (2020) reported a one-step and simple method for synthesizing sulfur-doped GQDs (S-GQDs) using PLAL process. It was observed that these S-GQDs exhibited an increased fluorescence quantum yields from 0.8 to 3.89% and excellent photostability. This method of preparing S-GQDs will open up new avenues for their potential applications.

4.4.2 Graphene-based quantum dots

Russo et al. (2014) developed a method for mass production of porous graphene (PG) and GQDs. They used femtosecond LA of highly oriented pyrolytic graphite for this purpose. It was observed that PG layers float at the water−air interface, and on the contrary, GQDs were found dispersed in the solution. It was confirmed that GQDs have dimensions in the range of 2−5 nm. They explained the formation of these materials on the basis of mechanisms, which involved coal gasification and water breakdown.

Habiba et al. (2015) fabricated GQDs (Ag-GQDs) decorated nanocomposites of silver NPs using pulsed laser. Then these nanocomposites were PEGylated, increasing their solubility in aqueous solutions and biocompatibility. The size of GQDs was in the range of 1.6−4 nm. The antibacterial activity of as-synthesized Ag-GQDs was evaluated and compared against Gram-negative (*Pseudomonas aeruginosa*) and Gram-positive bacteria (*S. aureus*) and it was found high as compared to and that of GQDs and

commercial silver NPs (Ag-NPs). It was reported that cell viability was maintained at 100% for normal mammalian cells, which were incubated with Ag-GQDs. As-prepared Ag-GQDs have potential applications in self-sterile textiles, antibacterial coatings, and personal care products.

Narasimhan et al. (2017) synthesized high-quality water-soluble GQDs using a ns pulsed laser and used these GQDs as fluorescent imaging agent. Their emission properties were attributed to the functional groups such as hydroxyl and carboxyl groups on the surface or edges. A deep red fluorescence was observed from the implanted region.

Santiago et al. (2017) synthesized N-doped GQDs using pulsed LA with diethylenetriamine (DETA). As-synthesized N-doped GQDs had an average size of about 3.4 nm and its atomic ratio (N/C) was 26%. It was reported that N-doped GQDs emitted PL with a factor 66 as compared to pristine GQDs. GQDs were synthesized by Calabro et al. (2018) via chemical oxidation of carbon nanoonions (nCNOs) followed by pulsed LA of these nCNOs to give CO-GQDS. Average diameter of these CO-GQDs was found to be 4.1 nm.

Novoa-De León et al. (2019) synthesized nitrogen-doped GQDs (N-GQDs) using PLAL. They ablated graphite target in dimethylformamide (solvent and nitrogen source, both). It was observed that these N-GQDs consists of a graphitic core with particle size of about 3 nm as well as oxygen and nitrogen functionalities. They used as-prepared N-GQDs dispersion for selective detection of ascorbic acid via a signal-on and signal-off system. These N-GQDs could also be used as PL sensor for metal ions.

4.5 Others

Goodwin et al. (1997) synthesized nanocrystalline GaN via reactive LA of gallium metal in nitrogen atmosphere. It was observed that these crystallites were as small as 2 nm (diameter). It was revealed by size-selective PL and PL excitation spectroscopy that there is a continuous range of blueshifted emissions and absorptions as compared to bulk value for gallium nitride.

Wu et al. (2005) synthesized semiconducting nanocrystals using picosecond pulsed LA. The crystalline nanometer-sized Si particles with average sizes ranging between 1−5 nm exhibited strong quantum confinement effects. Raman spectra confirmed the crystalline nature of these NPs, which showed significant shifts due to confinement. It was revealed that these quantum dots are promising candidates for solar cells.

Yoon et al. (2005) fabricated amorphous GaN quantum dots (a-GaN QDs) at room temperature using a LA technique and densified GaN target. An average particle size of as-prepared a-GaN QDs was found to be 7.9 nm. It was revealed that PL and absorption spectra exhibited a strong emission band centered at 3.9 eV, which was slightly shifted (0.5 eV), that is, a blueshift from the bandgap energy of the GaN crystal. This shift confirmed the

quantum confinement effect. Almeida et al. (2009) reported a LA route for synthesis of thiol capped CdTe colloidal quantum dots. They opined that these NPs were compatible for silica capping, which indicated that they could find application as fluorescent markers.

Qin et al. (2011) carried out Cu doping of ZnO quantum dots by LA of Zn/Cu composite targets immersed in PVP aqueous solution. Firstly, Zn/Cu core−shell particles were synthesized by a galvanic replacement reaction, followed by LA. It was reported that a large amount of Cu-doped ZnO QDs could be produced with ultrafine size, high stability, and good dispersibility. They also controlled dopant concentration (1.8%−4.8%) by just changing the atomic content of Cu in Zn/Cu composite targets. Zakharko et al. (2011) reported synthesis of luminescent SiC quantum dots using LA in pure deionized water. A higher colloidal stability was present for these laser-produced NPs. Long-term stability of colloidal solutions (as-prepared SiC quantum dots) is due to surface charges related to carboxylate anions. It was observed that emission from the Se QDs is centered at 2.75 eV and it does not depend on the laser power used for ablation.

Bagga et al. (2013) reported the synthesis of protein-functionalized luminescent silicon NPs using infrared ultrafast LA. They used silicon in an aqueous solution of *S. aureus* protein A for this purpose. Quantum dots of protein A-capped silicon (8 nm) were obtained with blue−green photoemissions. The biological functionality of these QDs was also studied by them. It was revealed that these Si-based bionanostructures bind IgG selectively in the cells, and therefore, these quantum dots may be suitable for biological applications, such as biomarkers for in vivo applications such as cell labeling, cell staining, and controlled drug delivery.

Gongalsky et al. (2016) reported a secondary toxicity problem of solution of brightly luminescent water-dispersible Si-based QDs using laser-assisted synthesis. These QDs do not exhibit any sign of toxicity; rather they show excellent cellular uptake and biodegradability making them an ideal candidate for bioimaging applications. Rodio et al. (2016) prepared amine-terminated, ultrasmall silicon NPs (Si NPs) in one step by introducing organosilane in Si NPs colloidal solution, which was prepared by ultrafast LA. It was confirmed that the successfully functionalized Si NPs was leading to 5 nm Si dots covered by a thick layer aminopropyltriethoxysilane. Such particles can find some biomedical applications such as biolabels, clinical setting, vector delivery, and contrast agents.

Rasouli et al. (2017) reported that the efficiency of photovoltaic solar cells can be increased by luminescent Si NPs. Sub Si NPs (10 nm) were synthesized using a pulsed LA technique. As-prepared ultrasmall Si NPs show PL characteristics at 517 and 425 nm upon excitation by UV light. The polycrystalline commercial solar cells are coated with these luminescent Si NPs giving an efficiency of about 10%.

Ren et al. (2018) synthesized black phosphorus quantum dots (BPQDs) using pulsed LA. They used isopropyl ether as a solvent. It was reported that QDs have average diameter of about 6 nm and also a height of about 1.1 nm. It was revealed that the PL quantum yield of as-prepared sample was about 20.7 %, which was almost three times higher than that of BPQDs prepared by some other means, for example, ultrasonic exfoliation (about 7.2 %). A stable and blue−violet emission was observed with BPQDs. Apart from it, BPQDs are also utilized in bioimaging in HeLa cells, with excellent biocompatibility. It was also revealed that as-obtained BPQDs have promising potential for biomedical applications, such as bioimaging, biolabeling, and drug delivery.

Most of the methods for synthesis of boron nitride quantum dots (BNQDs) are either complex or time-consuming. Xu et al. (2019) synthesized few-layer BNQDs by liquid-phase ultrashort laser pulse ablation and ultrasonic-assisted exfoliation methods. It was revealed that as-prepared BNQDs have an average size of about 2.1 nm. These BNQDs exhibited bright luminescence emission in the presence of UV light due to abundant surface functional groups. Anjana et al. (2020) prepared Er, Yb-codoped fluorapatite NPs using liquid-phase pulsed LA. A transparent colloidal solution had NPs sizes in the range of 2−4 nm. It was claimed that as-synthesized NPs dispersed in water are biocompatible and can find applications for cell imaging.

Morozova et al. (2020) focused on the possible use of silicon quantum dots ranging from 1 to 10 nm for LED. These QDs have a great potential as optoelectronic devices and fluorescent biomarking agents as they can exhibit blue and red fluorescence. Their biocompatibility compared to conventional toxic group II−VI and III−V metal-based quantum dots makes their practical utilization even more attractive to prevent environmental pollution and harm to living organisms. Sergeev et al. (2020) observed that coupling of HgTe QDs with lattice plasmons decreases the influence of nonradiative decay losses and IR absorption bands of dodecanethiol, which was used as a ligand on the QDs. It was reported that the ease of chemical synthesis and processing of HgTe QDs along with scalability of the direct laser fabrication of nanoantennas with tailored plasmonic responses helps in designing IR-range devices for different applications such as detectors, emitters, sensors, and security systems.

It is bit difficult to tune the PL properties of BNQDs and obtain these QDs with intense and desired PL emission. Recently, Nguyen et al. (2021) proposed a method to synthesize and functionalize BN QDs using femtosecond LA in an organic solution with tunable PL from ultraviolet to green region. It is all due to carbene zigzag edges, which are formed on the surface of BNQDs resulting in effective emission. There is a redshift in colors by increasing the content of carboxyl group on the carbene zigzag edges.

Soliman et al. (2021) synthesized stainless steel grade 304 QDs through LA in water. These were then used in the treatment of laryngeal carcinoma in vitro, without using any external laser source or magnet for hyperthermia. It was revealed that valence of chromium is +3 in these QDs and these show a resonance fluorescence property in the NIR band. It was observed that a dilute solution of QDs, on addition to cell culture medium, suppressed VEGF gene expression and cell proliferation; both of which indicated the death of cancer cells. The +3 valence of Cr and lower percentage of QDs exclude any possibility of QDs toxicity. The most plausible mechanism for death of cancer cells is due to heat shock of NIR resonance fluorescence of QDs.

4.6 Recent developments

LA is a fast-growing technique for the preparation of quantum dots. Some recent advances in this direction are shown in Table 4.1.

TABLE 4.1 Preparation of quantum dots by laser ablation.

Quantum dots	Application	References
Graphene	2D Material defect engineering	Li et al. (2021)

4.7 Conclusion

Various metals and metal chalcogenides quantum dots can be easily prepared by the LA method. It is equally effective in the preparation of carbon and GQDs. These quantum dots have a very high degree of purity as no chemical is added from outside and a target is exposed to the laser. This method of synthesis is welcome because it provides high-purity quantum dots and in a shorter time; however, the high cost of the equipment is still a concern. This method of synthesis will surpass all other methods in the forthcoming decades.

Chapter 5

Coprecipitation synthesis of quantum dots

Monika Jangid and Seema Kothari
Department of Chemistry, PAHER University, Udaipur, Rajasthan, India

5.1 Introduction

The coprecipitation method is used to prepare uniform compositions in homogeneous solution of two or more ions through precipitation reaction. It is an important method for the synthesis of some materials containing two or more elements. What is the difference between the precipitation and coprecipitation? The process of precipitation is the settling down of some insoluble particles from a homogeneous solution. This insoluble compound forms precipitates. Whereas coprecipitation is a process, where normally soluble compounds are thrown out of solution in the form of a precipitate. The coprecipitation is most commonly used for synthesis of nanoparticles and quantum dots (QDs). Different operational parameters like material, pH, concentration of the initial solutions, reaction temperature and time play important roles in getting nanoparticles or QDs with the desired shapes and sizes.

It is a simple, economical, and industrially viable technique that is normally used for the synthesis of important oxide materials. The various steps involved in this process are shown schematically in the flow chart in Fig. 5.1. It is possible to prepare flowable powders using this process without any additional agglomeration steps. One can tailor such a process to obtain nano- or microsized particles by adjusting the pH, temperature, solvents, and the precipitating agent.

5.1.1 Advantages

1. It is a most useful method for controlling the sizes of nanoparticles.
2. It is commonly used in the biomedical applications, because it is easy to apply and almost harmless.

Quantum Dots. DOI: https://doi.org/10.1016/B978-0-12-824153-0.00005-7
© 2023 Elsevier Inc. All rights reserved.

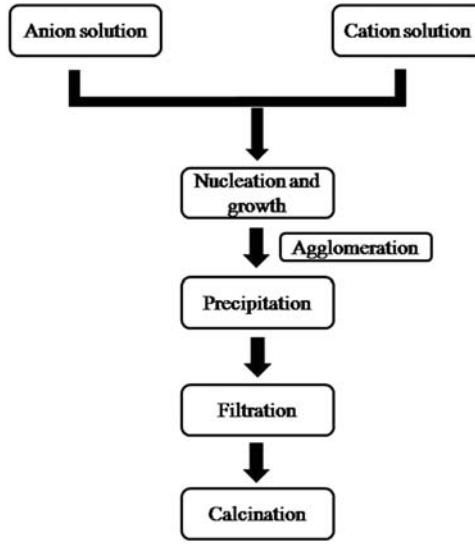

FIGURE 5.1 Flow chart of coprecipitation method.

3. In this method, nanoparticles are prepared from aqueous salt solutions, just by adding a base under an inert atmosphere at room temperature as well as at high temperatures.
4. It can be carried out at lower reaction temperature and with shorter reaction time.

5.1.2 Disadvantages

1. In this process, there in a problem because some undesired impurities may also coprecipitate with the analyte.
2. Distribution of shape of nanoparticles may be uncontrollable and size may be irregular.
3. The products are generally insoluble because of the high supersaturation condition, which is necessary to induce precipitation.
4. Salts may have similar solubilities.
5. It is often difficult to have material of high purity and accurate stoichiometry.
6. It is not cost effective in some cases.
7. One of the troubles with this method of synthesis of nanoparticles is the tendency of particles to agglomerate.

5.2 Classification of coprecipitation

Mainly, there are four types of coprecipitation:

1. surface adsorption;
2. mixed−crystal formation;
3. occulation; and
4. mechanical entrapment.

Out of these four, surface adsorption and mixed-crystal formation are equilibrium processes, while occulation and mechanical entrapment are due to the kinetics of crystal growth.

1. *Surface adsorption*: It is a common method of coprecipitation. Here, a significant contamination of precipitates occurs with large specific surface areas (coagulated colloids). Coagulation of a colloid does not decrease the amount of adsorption significantly. Therefore, the overall effect of surface adsorption is carrying down of an otherwise soluble compound as a surface contaminant.
2. *Mixed−crystal formation*: In this type of coprecipitation, one of the ions in the crystal lattice of a solid is replaced by an ion of another element. The extent of mixed-crystal contamination obeys the law of mass action and increases as the ratio of contaminant to analyte concentration increases.
3. *Occulation entrapment*: When a crystal is growing rapidly during precipitation formation, foreign ions in the counter ion layer may become trapped or occluded within the growing crystal. Occlusion is a type of coprecipitation, in which a compound is trapped within a pocket formed during rapid crystal growth.
4. *Mechanical entrapment*: Mechanical entrapment occurs when crystals lie close together during growth. Occlusion and mechanical entrapment are confined to crystalline precipitate. Both are at a minimum when the rate of precipitation formation is low.

5.3 Synthesis of quantum dots

5.3.1 Metal oxide quantum dots

Jbara et al. (2017) used the coprecipitation technique to synthesize gamma-Al_2O_3 (γ-Al_2O_3) nanopowders. As-prepared alumina nanopowders have particle diameter from 6−24 nm, as evident from XRD. Almost all particles were spherical in shape, but some particles acquired more regular hexagonal shapes on increasing annealing temperature, maybe due to agglomeration of nanoparticles. Zhao et al. (2018) synthesized graphene oxide/Mg-doped ZnO/tungsten oxide QDs composites via the coprecipitation method. It was reported that this composite exhibited photocatalytic activity that was almost 6.58 times higher than that of the composite without tungsten oxide. Transition-metal (Cr, Mn, Fe, Co, and Ni)- doped SnO_2 QDs were synthesized by Sharma et al. (2020) using the coprecipitation method. These QDs were capped by polyvinyl pyrrolidone. The size of as-synthesized particles was found to be 2.5 nm.

Sarkar et al. (2020) synthesized carbon-quantum-dot-embedded iron oxide nanoparticles (CQD@Fe_3O_4 NPs). The Fe_3O_4 NPs and CQD@Fe_3O_4 NPs were synthesized by the wet chemical coprecipitation method. A nearly spherical structure with an average size of about 7 nm was obtained for Fe_3O_4, while CQDs were around 2 nm in size in CQD@Fe_3O_4 NPs as evident from HRTEM. Hernandez et al. (2020) synthesized Fe_3O_4 MNPs modified with three different amino acids (AA): L-tryptophan, l-phenylalanine, and l-tyrosine via the coprecipitation method without using a spacer agent. This nanocomposite has high stability and good dispersibility in water and can be used in various biomedical and environmental applications.

Ragupathi et al. (2021) used the coprecipitation method for the synthesis of ZnO QDs and MPS organosilane modified ZnO@MPS. It was observed that as-prepared ZnO QDs and ZnO@MPS exhibited size reduction, better dispersion, and lower aggregation as compared to ZnO QDs. They also studied the antibacterial activities of these against *Staphylococcus aureus*, *Escherichia coli*, *Klebsiella pneumoniae*, and *Enterococcus faecalis*, and observed that ZnO@MPS QDs exhibited significant zones of inhibition, which may be due to smaller particle size.

Masmali et al. (2022) used ZnO and $ZnFe_2O_4$ as working electrodes in the QDs sensitized solar cells (QDSSCs). It was observed that $ZnFe_2O_4$ can enhance light absorption and its bandgap is 2.12 eV. They synthesized ZnO and $ZnFe_2O_4$ nanoparticles via coprecipitation. As-prepared mesoporous thin films of ZnO and $ZnFe_2O_4$ were sensitized with Ag_2S and CdS and then used as photoanodes in QDSSCs. It was revealed that Ag_2S sensitized photoanodes exhibited higher charge carrier resistance, shorter electron lifetime, and low fill factor as compared to CdS-based photoanodes.

Niu et al. (2022) prepared Cu_2O/SnO_2 QDs/ZnO arrays pn junction via a continuous sputtering−hydrothermal−coprecipitation method. It was reported that the as-prepared transparent photovoltaic device exhibited high transmittance ($\sim$80%) and photovoltaic enhancement ($\sim 1.5 \times 10^{-3}$ folds) (PCE = 1.03%), It was attributed to SnO_2 QDs, which have appropriate Fermi level increasing the charge carrier concentration/mobility, but high transparency was balanced.

5.3.2 Metal sulfides

Cadmium sulfide QDs were synthesized by Mishra et al. (2011) via a coprecipitation method. X-ray diffraction revealed that cubical zinc blend structure was present in CdS nanoparticles. It was found that CdS QDs are of 2−5 nm in size as evident from TEM data. A blue shift of 0.48 eV UV−V is absorption data was observed that compared to bulk CdS. Rahdar et al. (2012) synthesized ZnS:Cr nanoparticles by the coprecipitation method. It was possible to prepare different sized ZnS:Cr nanoparticles using this simple chemical method using different molar concentration of doping agent. They observed

that mean crystallite size of these particles ranged between 1.5 and 2.45 nm, which depended on the molar concentration of the doping agent.

Giribabu et al. (2012) synthesized $Cd_1 - _xMg_xS$ nanoparticles by the coprecipitation method. It was revealed that the structural phase transition is present from cubic to hexagonal and there is an increase in the average size of the nanoparticles (range 1.4−2.8 nm) on increasing content of Mg. The ZnS QDs along with their Be^{2+} and Mg^{2+} derivatives ($Zn_{1-x}Be_xS$ and $Zn_{1-x}Mg_xS$) were prepared by Iqbal and Iqbal (2013) via the coprecipitation route. The synthesized QDs are stable for a period of up to 7 months. It was found that particles were having cubic closed packed structure with an average particle size of 2−3 nm. It was proposed that these QDs may find applications in light-emitting diodes, sensors, coatings, and phosphor.

Zinc sulfide QDs (pure and doped with Fe^{3+}) were prepared by Shamsipur and Rajabi (2014) via a chemical coprecipitation method. The effect of different operational parameters on the decolorization of methyl violet, such as pH, initial dye concentration, dopant content, dosage of nanophotocatalyst, and UV irradiation time, were studied. It was observed that doping of ZnS QDs with Fe^{3+} enhanced its efficiency, as evident from the increased rate of dye removal. Rofouei et al. (2015) synthesized ultrasmall glycine dithiocarbamate (GDTC)-functionalized manganese doped ZnS (GDTC-Mn:ZnS) QDs via the coprecipitation method. It was then used as a sensor for cerous ions in concentration range of 2.0×10^{-6} to 3.2×10^{-5} mol L^{-1}, with a detection limit of 2.29×10^{-7} mol.L^{-1}. Tyagi et al. (2014) synthesized size tunable cadmium sulfide QDs via wet chemical coprecipitation method at pH 9 and 10.5 and different temperatures, that is, 35°C, 50°C, and 65°C. They used cadmium chloride and thiourea as precursors, while ammonium hydroxide was used as a precipitating agent and mercaptoethanol as a surfactant.

Elavarthi et al. (2016) synthesized undoped and Cr-doped CdS nanoparticles via the coprecipitation method. The average particle size was found to be 4−5 nm. Yadav et al. (2016) prepared copper-doped $Cd_1 - _xZn_xS$ QDs using a chemical coprecipitation method. The Cu-doped QDs have an hexagonal structure with average crystallite size in the range 2−12 nm. Sakthivel and Muthukumaran (2016) synthesized $Zn_{0.98} - _xCu_xMn_{0.02}S$ QDs (Cu and Mn codoped) with different copper concentrations (where $x = 0$, 0.02, 0.04) through a coprecipitation technique. The $Zn_{0.98}Mn_{0.02}S$ was in the cubic phase, which gives a mixture of cubic as well as hexagonal phases on Cu-doping. The bandgap was found to range between 3.3 and 3.93 eV on Mn and Cu codoping. These codoped zinc sulfide QDs can find use in optoelectronic devices. Youngjin and Jongsung (2016) prepared silica nanospheres containing magnetic particles. Then CdSe/ZnS QDs were functionalized and incorporated into these silica nanospheres. It was reported that fluorescence from as-prepared QDs was quenched and this magnetic silica−QD−DNA probe can be used to detect a particular DNA.

The $Zn_{0.98-x}Ni_xMn_{0.02}S$ QDs were synthesized by Sakthivel and Muthukumaran (2017) via a coprecipitation method. They reported that the average crystallite size was 1.3−1.8 nm. A red shift was observed in absorption and intensity was increased on increasing concentration of Ni. The bandgap of as-prepared samples ranged between 3.56 and 3.93 eV. As-prepared material can be used in optoelectronic devices and also as a buffer material in solar cells. Zinc sulfide QDs and transition metal-doped ZnS nanocrystals were prepared by Jabeen et al. (2017) by a coprecipitation method.

Zhang et al. (2017) synthesized hybrid rGO/$CoFe_2O_4$/ZnS nanocomposites via a combination of hydrothermal and coprecipitation route. It was reported that ZnS QDs and $CoFe_2O_4$ nanoparticles had an average diameter of 3−8 and 10−20 nm, respectively, and these were anchored on graphene sheets. It was proposed that the as-prepared nanocomposites have a potential for use in stealth camouflage techniques.

Kaur et al. (2017) synthesized ZnS QDs via a coprecipitation technique. They used sodium dodecyl sulfate as a stabilizing agent. They used these ZnS QDs as a photocatalyst for degrading brilliant green under sunlight. They could achieve about 88% degradation of brilliant green.

Desai et al. (2018) synthesized PVP-coated ZnS nanoparticles doped with transition metals by a wet chemical coprecipitation method. The average particle size of these PVP−ZnS nanoparticles was around 2.6 nm. Cobalt-alloyed ZnS QDs were synthesized by Horoz (2018) via a coprecipitation method. It was found that Cobalt-alloyed ZnS QDs had a cubic structure with size 2.71 nm, which is little bit smaller than the size of pure ZnS QDs (2.72 nm). It was revealed that there was a blueshift compared to pure ZnS QDs.

Ashokkumar and Boopathyraja (2018) prepared $Zn_{1-x}Mg_xS$ QDs by a coprecipitation method. It was observed that Mg dopant did not affect the cubic blende structure of ZnS QDs. The average crystallite size increases from ∼1.7−2 nm at initial doping of Mg (20%). It was revealed that the bandgap of the QD was decreased at initial doping of Mg due to the quantum confinement effect but at a higher doping level the bandgap was found to be increased. Sakthivel and Muthukumaran (2018) prepared Cobalt-alloyed (0%−4%) $Zn_{0.98}Mn_{0.02}S$ QDs by a coprecipitation method. It was found that the average crystallite size of the particles was around 3 nm. It was reported that average crystallite size of as-prepared QDs was ∼3 nm. Rafiq et al. (2019) prepared ZnS QDs via the coprecipitation method. They used 2-mercaptoethanol as a capping agent. An average crystallite size of ZnS QDs was found to be 4.2 nm. These uncapped ZnS QD were used for photocatalytic degradation of methylene blue.

Mansur et al. (2019) prepared fluorescent ternary and quaternary QD nanostructures based on $AgInS_2$ core and ZnS shell. These QDs were stabilized with carboxymethyl cellulose polymer ligand. They prepared colloidal $AgInS_2$ QDs by a coprecipitation process. Sizes of $AgInS_2$ and $AgInS_2$/ZnS

QDs range were in the of 8.5 ± 2.4 nm and 3.2 ± 1.1 nm under acidic or alkaline media, respectively. Yu et al. (2019) used chitosan (CS) as a biomacromolecule model and surface ligands to synthesize CuS QDs via the coprecipitation method. These CuS-CS QDs were conjugated with folic acid (FA). It was reported that the size of CuS-CS-FA QDs was around 4 nm. It was revealed that CuS-CS-FA QD can be effectively targeted and accumulated in the tumor reaching the peak dose in 1 h, when CuS-CS-FA QDs dispersion was injected (intravenously) into the tumor-bearing mice.

Devadoss et al. (2019) synthesized Zn, Cr codoped CdS QDs via a coprecipitation method. They carried out this synthesis at room temperature without using any capping agent. It was observed that samples have cubic structures, which remained unaffected by the presence of Cr, but the crystallite size was found to be reduced in the order of ~2 nm. The presence of Cr was considered responsible for a blueshift. The ZnS QD (Mg, Mn codoped) were synthesized by Sakthivel et al. (2019) using a coprecipitation method. The particle size in the range of ~2 nm. A redshift was observed with an increase in Mg doping concentration, which will reduce the bandgap.

Meng et al. (2020) synthesized cadmium sulfide QDs through the coprecipitation method. It was observed that there was a blue shift of 0.48 eV compared to that of bulk CdS. The particles size of CdS QDs was found to be 3.665 nm. Abha et al. (2020) synthesized Mn:ZnS/BSA QDs by a chemical coprecipitation method. It was reported that Mn:ZnS/BSA QDs can serve as an effective sensor platform for dopamine. The luminescence of Mn:ZnS/BSA QDs was found to decrease linearly with increasing concentration of dopamine in the range from 6.6 to 50.6 nM.

Ibraheema et al. (2020) synthesized the ability to tune the paramagnetic effect of Co-doped CdSQDs, which were prepared by a coprecipitation route with varied Co^{2+} concentrations. It was reported that the highest possible paramagnetic effect in the CdS semiconducting matrix exhibited bandgap in the visible range (2.76 eV). Sharma et al. (2021) prepared polyvinlypyrrolidone (PVP) capped CuS QDs ($Cu_1 - _xTM_xS$) via the chemical coprecipitation route. They also doped these QDs with some magnetic transition metals (TM = Fe, Cr and Co).

5.3.3 Metal selenide quantum dots

CdSe QDs were synthesized by Verma et al. (2016) via the chemical coprecipitation method. It was revealed that the cubic phase of the crystalline CdSe transformed to stable hexagonal phase at 317°C and the average particle size of these QDs ranged between (3−5 nm).

Lewis et al. (2016) synthesized semiconducting heterostructures composed of cadmium selenide QDs attached onto the surfaces of Eu-doped and Pr-doped $CaTiO_3$. It was observed that 2.7-nm diameter ligand-functionalized CdSe QDs were attached to $CaTiO_3$-based spherical assemblies. Ag_2Se QDs were prepared

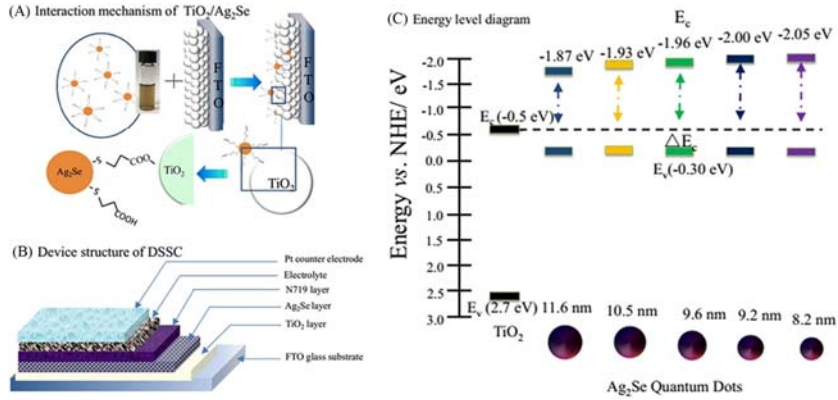

FIGURE 5.2 Dye sensitized solar cells using Ag_2Se quantum dots. *Adapted from Zhang, Z., Yang, Y., Gao, J., Xiao, S., Zhou, C., Pan, D., et al., 2018. Highly efficient Ag_2Se quantum dots blocking layer for solid-state dye-sensitized solar cells: size effects on device performances. Mater. Today Energy 7, 27–36 with permission.*

by Zhang et al. (2018) using a coprecipitation method and then used in solid-state dye-sensitized solar cells (Fig. 5.2). It was revealed that monodispersed Ag_2Se QDs had average sizes ranging between 8.2–11.6 nm. The highest power conversion efficiency of Ag_2Se QDs (9.6 nm)-based solar cells was reported to be 5.89%.

5.3.4 Carbon-based

A graphene QDs and CoNiAl-layered double-hydroxide composite was synthesized by Samuei et al. (2017) through a coprecipitation method. They fabricated a modified carbon paste electrode containing this nanocomposite that was used as a nonenzymatic sensor for determination of glucose. It was reported that the as-prepared sensor offered high reproducibility, fast response time, good electrocatalytic properties, and stability. It was revealed that the as-constructed sensor exhibited sensitivity in a wide range of concentrations of glucose (0.01–14.0 mM) with a limit of detection of 6 μM.

It was revealed that the $NiFe_2O_4$/GQD sample exhibited the highest catalytic activity and completed the reduction in a minute to afford p-aminophenol. The catalysts displayed good stability, can be recovered using a magnetic field, and can be recycled for six experiments with a conversion percentage of >95%.

Sharma et al. (2018) prepared iron nanoparticles, Fe@carbon QDs, and Fe/Ag@carbon QDs nanocomposites by a simple coprecipitation/reduction method. The photocatalytic activity of Fe, Fe@CQDs, and Fe/Ag@CQDs was evaluated for the removal of fast green dye. The catalytic nature of as-synthesized materials was also investigated for the esterification of acetic

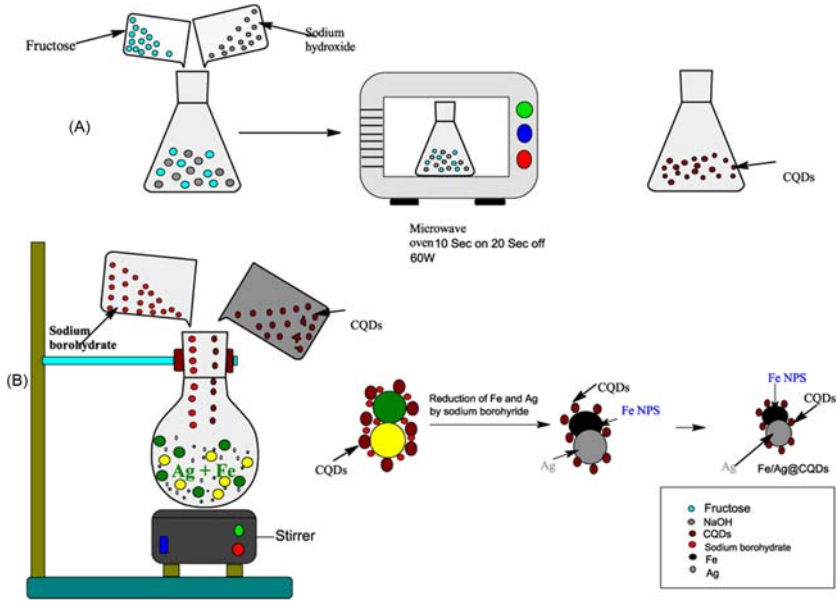

FIGURE 5.3 Use of iron-based quantum dots and nanocomposites for degradation, oxidation, and esterification. *Adapted from Sharma, G., Kumar, A., Naushad, M., Kumar, A., Ala'a, H., Dhiman, P., et al., 2018. Photoremediation of toxic dye from aqueous environment using monometallic and bimetallic quantum dots based nanocomposites. J. Clean. Product. 172, 2919–2930 with permission.*

acid and oxidation of benzyl alcohol (Fig. 5.3). It was reported that oxidation of benzyl alcohol with H_2O_2 with Fe NPs gave the highest yield (87%), while esterification of acetic acid with different alcohols (ethyl, isopropyl and butyl) showed that butyl alcohol gave a maximum yield of 82%, 80%, and 84% with Fe NPs, Fe@CQDs, and Fe/Ag@CQDs, respectively.

Lin et al. (2019) anchored nitrogen-doped carbon QDs (NCDs) and graphitic carbon nitride QDs (CNQDs) on the surface of $BiVO_4$ microspheres to fabricate $BiVO_4$/CNQDs/NCDs composite via the coprecipitation method. It was reported that as-synthesized $BiVO_4$/CNQDs/NCDs exhibited an excellent photocatalytic activity for the degradation of rhodamine B as well as tetracycline under UV illumination as compared to pure $BiVO_4$, $BiVO_4$/CNQDs, and $BiVO_4$/NCDs (Fig. 5.4).

5.3.5 Graphene-based

Wu et al. (2014) prepared composites of GQDs and Fe_3O_4 nanoparticles (GQDs/Fe_3O_4) via a coprecipitation method. It was reported that as-prepared GQDs/Fe_3O_4 composites exhibited a better stability and reusability as compared to natural peroxidases. This GQDs/Fe_3O_4 composite was also used as

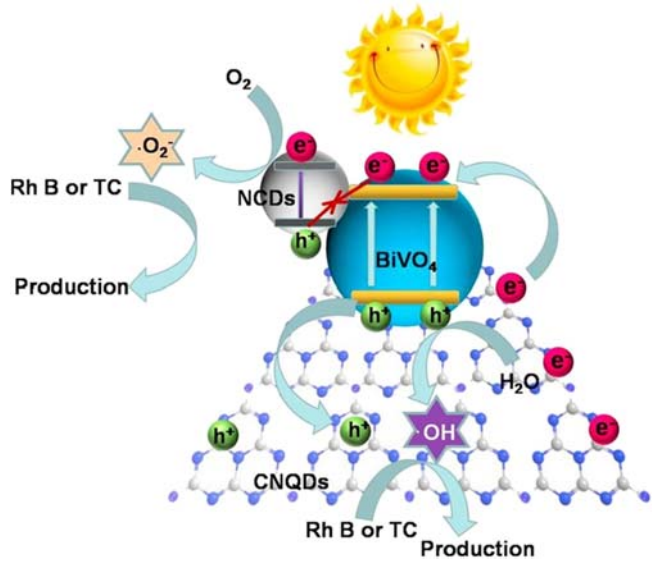

FIGURE 5.4 Use of $BiVO_4$/CNQDs/NCDs composite for degradation of rhodamine B and tetracycline. *Adapted from Lin, X., Liu, C., Wang, J., Yang, S., Shi, J., Hong, Y., 2019. Graphitic carbon nitride quantum dots and nitrogen-doped carbon quantum dots co-decorated with $BiVO_4$ microspheres: a ternary heterostructure photocatalyst for water purification. Sep. Purif. Technol. 226, 117–127, 2019, with permission.*

a catalyst for the removal of phenolic compounds (nine in all). It showed better or sometimes comparable removal efficiencies for phenolic compounds as compared to native horseradish peroxidase.

Ramachandran et al. (2018) developed a method for the synthesis of graphene QDs/cobalt ferrite nanocomposite. They synthesized graphene QDs using citric acid, which was followed by coprecipitation of cobalt ferrite nanoparticles on these graphene QDs. It was reported that as-synthesized nanocomposite exhibited good superparamagnetic properties and fluorescence, which are useful in biomedical applications.

Naghshbandi et al. (2018) synthesized graphene QDs and metal ferrites (MFe_2O_4; where, M = Ni, Co) nanocomposites via a coprecipitation method. They used these nanocomposites as catalysts in the reduction of p-nitrophenol. It was reported that the $NiFe_2O_4$/GQD composite exhibited the optimum catalytic activity and the reduction of p-nitrophenol was completed within 1 min. It was revealed that these catalysts can be separated by a magnetic field using an external magnet. They also show good stability and these can be reused for six cycles retaining activity of around 95%.

The catalytic activity of as-prepared nanocomposites and metal ferities for the reduction of p-nitrophenol was found to follow the order:

$$NiFe_2O_4/GQD > CoFe_2O_4/GQD > NiFe_2O_4 > CoFe_2O_4.$$

Zhao et al. (2021) synthesized graphitic carbon nitride QDs by incorporating the unique organic functional group of barbituric acid into the framework of the carbon nitride structure by supramolecular preorganization. Then three CNQDs were introduced onto basic zinc carbonate (BZC) surface via the coprecipitation method. It was reported that the as-prepared CNQDs/BZC composite exhibited a higher degradation efficiency of tetracycline, which was about 2.4 times higher than that of ZnO. It was revealed that $^{\bullet}O_2^-$ and $^{\bullet}OH$ radicals played major roles in degradation due to the suitable bandgap.

Hsieh et al. (2022) introduced N-GQDs in rGO, which efficiently facilitates the photocatalytic activity of composite. It was reported that an ultrahigh removal ratio ($\sim$100%) and improved rate constant could be achieved with this GQD/ZnO catalyst (1.74 more as compared to pristine ZnO). It was revealed that the presence of N-GQDs increased the absorption in the visible light region and photoinduced charge carrier, and as a result photocatalytic activity was increased. It was observed that as-prepared GQD/ZnO composite can be used as a photocatalyst for degrading metronidazole in the presence of UV−light irradiation.

5.3.6 Others

Lan et al. (2014) prepared hybrid nanocomposites of Zn-Cr layered double hydroxide (ZnCr-LDH) and graphene through a coprecipitation method. It was reported that ZnCr-LDH nanoplatelets had a diameter $\sim$6 nm and these were well dispersed on the graphene surface. These hybrid ZnCr-LDH/graphene nanocomposites were used for the photocatalytic degradation of rhodamine B, which has a higher rate as compared to ZnCr-LDH.

Bahadori et al. (2021) used a coprecipitation-assisted solvothermal method to synthesize covalent organic frameworks (COFs) QDs, which were modified with biochar. It was found that as-synthesized COFs QD nanostructures have an average size of about 3.68 nm. These nanocomposite structures were then utilized for decolorizing methyl blue, methyl orange, and methyl red.

5.4 Conclusion

Various QDs (metals, metal oxides, metal sulfides, carbon, and graphene-based materials) can be synthesized successfully using the coprecipitation approach. It is an eco-friendly and relatively low-cost approach to synthesize nanomaterials. It can also be used to prepare larger amounts of QDs on an industrial scale. As-synthesized QDs have great potential for application in varied fields of interest such as bioimaging, sensors, solar cells, water splitting, and light-emitting diodes.

6.1 Introduction

The synthesis of designer solid state materials by living organisms is an emerging field of research. As there is a growing trend in biomedical applications of quantum dots, biosynthesized nanomaterials are attracting the attention of researchers these days due to their biocompatible, low-energy consumption, economic, and tunable characteristics.

Zero-dimensional semiconductor quantum dots (<10 nm) have received great attention because of their potential use in biomedical applications (diagnosis and therapy), where larger nanoparticles (>10 nm) were not found to be suitable.

Biosynthesis of quantum dots is an alternate green method for the production of quantum dots with superior properties, such as tunable size, emission spectra, and a longer fluorescence lifetime. Biosynthesis of quantum dots offers other several advantages over other existing conventional chemical synthesis routes, such as low cost, eco-friendliness, and no need for any further modification of the products. Controlled monodispersity, chemical compositions, desired morphologies, and particle size could be achieved with the biosynthesis method.

However, still manipulation and control of biosynthesis of QDs remain slightly difficult because of the lack of knowledge of the mechanisms necessary for the biosynthesis or the effect of the biosynthesizing organisms is still insufficient.

Synthesis of QDs can be carried out using plants (*Avena sativa*, *Azadirachta indica*, *Alovera*, *Mangifera indica*, etc.) fungi (*Fusarium oxysporum*, *Phanerochaete chrysosporium*, *Pleurotus ostreatus*, etc.), bacteria (*Escherichia coli, Pseudomonas, Staphylococcus aureus, Acidithiobacillus*

Quantum Dots. DOI: https://doi.org/10.1016/B978-0-12-824153-0.00006-9

genus, etc.), and enzymes. There are many more plants, bacteria, enzymes, fungi, etc., which are still unexplored although they have a great potential for preparing quantum dots.

6.1.1 Advantages

1. It is a green chemical route.
2. It is relatively less time consuming.
3. Ambient conditions are required, and not harsh conditions.
4. It is based on natural materials such as plant extracts, enzymes, bacteria, fungi, etc.

6.1.2 Disadvantages

1. It is based on plants, which means a limited source.
2. It may cause additional problems, particularly when bacteria and fungi are used, unless carried out under control.
3. Difficult to control the size of nanocrystal.

6.2 Plants

Wang et al. (2005) prepared ZnS semiconductor nanoparticles in situ in chitosan film. It was revealed that the chitosan template was monodispersed and passivated. The average size was found to be 3.4 nm. Rosano-Ortega et al. (2006) synthesized Mn nanoparticles in the range of 1−4 nm using water hyacinth. It was reported that the as-obtained particles have a well controlled size. It was also revealed that small clusters in the range of 1−2 nm were generated, when the pH was kept at 5. It was also found that smallest aggregates with polyhedron shapes were stable in nature.

Wang et al. (2009) synthesized water-soluble biocompatible and monodispersed CdS, ZnS, and CdSe quantum dots using natural chitosan derivatives as stabilizers. It was revealed that nanoparticles with average size of 3−5 nm were obtained. It was found that the photoluminescence of QDs was enhanced and surface defects were passivated. It was found that the size of particles and photoluminescence intensity can be controlled by varying the concentration of precursor ions and stabilizer, refluxing the time and molar ratio of metal ions with sulfide. The resulting biopolymer/QDs composite can be potentially applied as a biosensor or fluorescence tags in biological systems. An efficient and green method for plant-based biosynthesis of CdS quantum dots has been reported by Borovaya et al. (2014). They used hairy root culture of *Linaria maroccana* L. for this purpose. The *Linaria* root extract was incubated with sodium sulfide and cadmium sulfate to give stable luminescent CdS nanocrystals. It was revealed that as-obtained QDs were spherical in shape with a size ranging from 5 to 7 nm. The wurtzite

crystalline structure of as-synthesized CdSQDs was confirmed by electron diffraction.

Bhattacharjee and Ahmaruzzaman (2015) synthesized SnO_2 QDs by a green biological route using sugar cane juice. It was predicated that biomolecules present in sugar cane juice act as both capping agent and complexing agent. It was observed that spherical SnO_2 quantum dots were obtained with particle size ranging between ~2.5 and 4.5 nm. It was revealed that a blue-shift in the bandgap energy was there with decreasing particle size. As-synthesized SnO_2 QDs were then used for photocatalytic degradation of methylene blue and rose Bengal under direct sunlight. The catalytic activity of these biosynthesized QDs was also evaluated for reduction of p-nitrophenol to p-aminophenol in the presence of sodium borohydride in water. It was revealed that 99.5% of p-nitrophenol was reduced in these conditions within 1 h.

Ouyang and Sun (2016) used wheat endosperm cells in the biosynthesis of Ag_2S QDs. The delivered precursors of QDs into cultured wheat endosperm cells provided Ag_2S QDs in an aging process under the effect of endogenous glutathione in the cells. It was observed that these intracellularly synthesized near-infrared (NIR) fluorescent QDs were highly photostable and can be used for bioimaging. The biosynthesis of HgTe quantum dots has been reported by Green et al. (2016) in a living plant via a mutual antagonistic reaction. It was observed that when *Allium fistulosum* was exposed to mercury and tellurium salts, it afforded crystalline HgTe quantum dots (nonpassivated) under ambient conditions. These QDs exhibited emission in the near-infrared spectral region, which is the suitable range for finding applications in solar energy conversion and telecommunications.

The hairy roots of tomato (*Solanum lycopersicum*) and also fission yeast (*Schizosaccharomyces pombe*) were used by Al-Shalabi and Doran (2016) for biological synthesis of CdS quantum dots. It was observed that the growth rate with hairy roots was much slower compared with yeast, so they can be utilized for large-scale production. It was revealed that CdS crystallites obtained with yeast were smaller in size (2−6 nm diameters) as compared to QDs obtained using the roots (4−10 nm diameters). Borovaya et al. (2016) prepared water-soluble CdS quantum dots. They used bright yellow-2 (BY-2) cell suspension culture for this purpose, which acted as both stabilizing and capping agent. It was indicated that CdS QDs were crystalline and spherical in shape, ranging from 3 to 7 nm (diameter). It was revealed that as-synthesized CdS QDs were almost nontoxic in low concentrations using *Nicotiana tabacum* protoplasts as a model.

A simple and eco-friendly method for biosynthesis of luminescent ZnO quantum dots (well dispersed) was reported by Kaviya et al. (2017) using pomegranate peel extract. The use of this method avoided the use of strong commercial stabilizing agents, higher temperature, pH conditions, and inert atmosphere. It was revealed the as-obtained ZnO QDs had an average size

distribution around 4 nm. These ZnO QDs were water soluble and found to be stable for almost 1 year. As the emission from ZnO QDs was quenched on adding Cr^{3+} ions, the presence of these ions can be detected up to 2 nM in aqueous solution. Silva et al. (2017) biosynthesized Ag quantum particles using *Eichhornia crassipes* biomass. It was reported that the shape, size, structure, and composition of QDs were dependent on the amounts of hydrolyzable tannins in this plant. It was revealed that the amounts of hydrolyzable tannins were highest in the leaves of this plant. These QDs were found to be nearly spherical in shape; however, these were mostly polyhedral. It was observed that leaf biomass could produce quantum dots with sizes <10 nm and these were mostly AgO, and not Ag.

Begum and Ahmaruzzaman (2018) used microwave heating for the biosynthesis of SnO_2 quantum dots using *Parkia speciosa* Hassk pods extract. As-synthesized SnO_2 QDs were then used as a photocatalyst for the degradation of acid yellow 23 (a food dye) in aqueous solution in the presence of UV254 light. It was reported that biosynthesized SnO_2 QDs could degrade acid yellow 23 with photocatalytic efficiency (98%) in 24 min. It was claimed that these SnO_2 QDs can be reused for up to five consecutive cycles without losing efficiency and stability. Shivaji et al. (2018) developed a green biogenic synthesis for preparing CdS QDs using tea leaf extract (*Camellia sinensis*). It was found that the particle size of QDs was in the range of 2−5 nm. They also investigated the biological activity of these CdS QDs and it was observed that they exhibited cytotoxicity toward A549 cancer cells. This activity was also compared with a standard drug, cisplatin, with comparable results.

An efficient and green approach was reported by Alvand et al. (2019) for synthesis of cadmium telluride quantum dots. They used an aqueous extract of fruits of *Ficus johannis* plant. Two extraction methods were used for extraction: (1) microwave-assisted extraction (MWAE) and (2) ultrasonic-assisted extraction (USAE). These plant extracts were used as natural stabilizing precursors for synthesizing CdTe QDs. The average particle size of as-prepared QDs was calculated as 1.2 nm. It was indicated that these CdTe QDs have negligible genotoxicity and toxicity impacts. Fatimah et al. (2020) biosynthesized SnO_2 quantum dots using flower extract of Aparajitha (*Clitoria ternatea*) as a reducing agent. This flower extract contains flavonoids as well as flavanols, which can reduce Sn^{2+} precursors into Sn° NPs, which are then oxidized to SnO_2 QDs (4−10 nm). A blueshift was observed in the wavelength of biosynthesized SnO_2 QDs. These QDs were there used for photocatalytic degradation of rhoadamine blue under UV irradiation.

Biosynthesis of CdS QDs has been reported by Gholami et al. (2020) using aqueous extracts of regenerated hairy roots of *Rhaphanus sativus* L. It was observed that as-obtained particles were spherical in shape with size ranging between 2 and 7 nm. It was also reported that these CdS QDs exhibited more apoptosis effect on MCF-7 breast cancer cells as compared to

AGS gastric cancer cell lines. Kandasamy et al. (2020) reported the synthesis of CdS quantum dots using fruit sap of *Opuntia ficus indica* (as green template). It was revealed that QDs were spherical in shape.

A green chemical route for the synthesis of copper quantum dots has been developed by Rani et al. (2020) using leaf extract of *M. indica* (L.). They used copper sulfate as the source of copper. It was proposed that a polyphenolic compound (mangiferin) in leaf extract of *M. indica* may act as a capping, reducing, and stabilizing agent during the preparation of Cu QDs. As-obtained Cu QDs were stable and spherical in shape with size ranging from 4−7 nm. It was reported that these Cu QDs can degrade methylene blue and possess higher antimicrobial activity and scavenging activity of free radical.

Zaman et al. (2020) reported the biogenic synthesis of cupric oxide nanoparticles using leaf and fruit extracts of *Tamarindus indica* L. These extracts acted as capping and reducing agents. It was observed that CuO quantum dots of size 5−10 nm could be obtained using fruit extract, but larger particles (50−100 nm) were obtained on using leaf extract. The photocatalytic activity of as-synthesized QDs was evaluated for the degradation of rhodamine B under UV−Vis light illumination. It was reported that QDs obtained with leaf extract could degrade 65% of rhodamine B in 2 h, while quantum dots prepared using fruit extract degraded 77% of the dye. These QDs exhibited an excellent photostability and in vitro antimicrobial activity against bacterial strains *S. typhi*, *E. coli*, and *L. acidophilus*.

Das and Dhar (2020) reported a method for the synthesis of tin dioxide quantum dots. They used the shoots of *C. sinensis* as a stabilizer and reducing agent. It was observed that as-prepared tin dioxide quantum dots had a flake-like morphology and were crystalline with an average size of 4.3 nm. As-obtained SnO_2 quantum dots were then used for photocatalytic degradation of thiamethoxam. They could achieve 57% degradation within 45 min.

The extracts of medicinal plants such as *Bryophyllum pinnatum*, *Mentha arvensis*, and *Dalbergia sissoo* were used by Kumar et al. (2021) to prepare Ag NPs by reducing silver nitrate. Then, Ag NP-conjugated L-cysteine-capped ZnS:Mn quantum dots were also fabricated, which exhibited antimicrobial activity against *E. coli* and *S. aureus*. This work may provide new avenues for synthesizing plasmonic NPs using nontoxic material to be used as detectors and biosensors.

The synthesis of CdS quantum dots was carried out by Tudu et al. (2021) using *Ocimum sanctum* (Tulsi) leaf extract. It was reported that the phytochemicals of Tulsi leaf extract played an important role in controlling particle size and morphology. The average crystallite size of these biosynthesized QDs was found to be in the range of 3.6−3.0 nm It is interesting to note that the bandgap of the capped CdS QDs increases with increasing extract concentration, but on the contrary particle size decreases.

Pugazhenthiran et al. (2021) prepared monodispersed silver quantum dots via a green synthesis method. They used sweet lime (*Citrus limetta*) peel

extract for this biosynthesis. It was reported that face-centered-cubic Ag QDs with size (<5 nm) were obtained. The presence of carbohydrate and citrate were considered responsible for the formation of small Ag QDs with good stability. It was also indicated that as-synthesized Ag QDs were able to cause the death of cancer cells (71%) even at a low concentration (100 $\mu g\ mL^{-1}$).

Raja and Sundaramurthy (2021) used betel leaves (piper betle) for green synthesis of fluorescent carbon quantum dots. They reported that as-prepared carbon dots were selective in the detection of Fe^{3+} ions in aqueous medium. They have detected successfully the presence of ferric ions even in the presence of interfering metal ions such as Ca^{2+}, Mg^{2+}, Cu^{2+}, Ag^{+}, Fe^{2+}, Hg^{2+}, Cd^{2+}, Fe^{3+}, and Pb^{2+} at the same concentrations. It was reported that it was possible to detect Fe^{3+} ions in the concentration range of 50−150 nM with high sensitivity.

6.3 Bacteria

A facile route for the synthesis of cadmium sulfide nanoparticles has been reported by Bai et al. (2009) using the photosynthetic bacteria *Rhodopseudomonas palustris*. It was observed that the cadmium sulfate solution incubated with *R. palustris* biomass changed its color to yellow after 2 days. As-obtained CdS nanoparticles had an average size of 8.01 ± 0.25 nm with uniform distribution, as evident from by TEM images. A bacterial synthesis for cadmium telluride quantum dots with tunable fluorescence emission has been reported by Bao et al. (2010a) using *E. coli*. It was observed that these QDs exhibited size-tunable optical properties with fluorescence emission at 488−551 nm. It was revealed that these biosynthesized QDs have great potential in a wide range of biolabeling and bioimaging applications.

Mi et al. (2011) prepared CdS quantum dots using genetically engineered *E. coli* by introducing foreign genes encoding a CdS binding peptide. They prepared CdS QDs through two methods: lysis, and freezing−thawing of cells. It was claimed that biologically synthesized CdS QDs may be more biocompatible probes in bioimaging and biolabeling. Suresh et al. (2011) reported an efficient synthesis of extracellular silver sulfide nanoparticles using the metal-reducing bacterium *Shewanella oneidensis*. It was observed that particles were homogeneously shaped, monodispersed, and produced with high yield (85%). It was also revealed that as-prepared particles were a spherical shape with a mean diameter of 9 ± 3.5 nm. As-fabricated QDs particles are biocompatible and dispersible. They have an excellent potential for application in electronic devices, optical imaging, and solar cells.

Jiang et al. (2012) prepared cadmium sulfide quantum dots via in situ crosslinked chitosan hydrogel films. It was confirmed that crosslinked chitosan hydrogel films provided a confined matrix for CdS QDs growth. As-prepared CdS QDs/chitosan composite films slow photocatalytic activity for

degradation of methyl orange solution in the presence of visible light. Luminescent CdSe quantum dots were synthesized by Fellowes et al. (2013). They used bacterially derived selenide (Se^{2-}) as the precursor. Biogenic Se^{2-} was produced by the reduction of Se(IV) by *Veillonella atypica*. It was reported that biological Se^{2-} formed smaller and narrower size distributed QDs as compared to borohydride-reduced Se(IV) under similar conditions.

Kominkova et al. (2014) evaluated the effect of CdTe quantum dots on *Collembolans*, the earthworm *Eisenia fetida*, and *E. coli*. They also studied the effect of biosynthesis of QDs in *E. fetida* and *E. coli*. It was revealed that biosynthesis in earthworms can be a protective mechanism of its own; while it is probably a by-product of protective mechanisms in *E. coli*. Yan et al. (2014) proposed a green and efficient biosynthesis method for preparing CdSe QDs using *E. coli* cells as biological matrix. These QDs were fluorescence-tunable and biocompatible. It was observed that there was a surface protein capping layer outside QDs, as evident from FT-IR data. It was suggested that as-prepared quantum dots may prove to be an excellent fluorescent marker for broad bioimaging and biolabeling.

Gallardo et al. (2014) isolated oxidative stress-resistant bacteria (*Pseudomonas* spp.) from Antarctica and then used them for biosynthesis of CdS QDs at 15°C. It was reported that there was a change in fluorescence color (green to red), which was found to be time dependent. Yang et al. (2015) engineered a bacterial strain for biosynthesis of CdS quantum dots. It was reported that extracellular and water-soluble CdS quantum dots were obtained on using this strain at ambient pressure and temperatures with low-cost precursors. The biosynthesis of α- and β- forms of ZnS quantum dots was developed by Yue et al. (2016) using *Clostridiaceae* sp. They used different concentrations of hydroxypropyl starch as dispersant in this process. It was indicated that as-obtained α-ZnS quantum dots had a wurtzite structure with a low dose of hydroxypropyl starch, while β-ZnS quantum dots were prepared with a sphalerite structure with a high dose. It was also revealed that β-ZnS quantum dots exhibited a redshift as compared to α-ZnS quantum dots.

Fluorescent *Bacillus subtilis* cells were developed as probes for imaging applications and to explore behaviorial interaction between *B. subtilis* and *S. aureus*. A controlled biosynthesis of CdSe quantum dots was developed by Yan et al. (2016) using living *B. subtilis* cells. It was reported that *B. subtilis* cells inhibit the growth of nearby *S. aureus* cells. Such inhibition was affected by both growth stage as well as amount of surrounding *B. subtilis* cells.

Ulloa et al. (2016) reported the biosynthesis of cadmium sulfide QDs using acidophilic bacteria *Acidithiobacillus genus*. These CdS QDs were obtained when *Acidithiobacillus thiooxidans*, *A. ferrooxidans*, and *A. caldus* cells were exposed to sublethal cadmium concentrations in the presence of glutathione and cysteine. It was revealed that fluorescence of cadmium-exposed cells moves from green to red with time of incubation. It was

reported that an average size of 6 and 10 nm was found to show green and red QDs, respectively.

Yan et al. (2017) reported a green biosynthesis of cadmium sulfide quantum dots. Here, *E. coli* was selected as a biomatrix. It was revealed that these CdS quantum dots emitted a blue−green fluorescence under UV excitation. It was indicated that the antibiotic resistance of *E. coli* had a slight decrease when CdS quantum dots were prepared at mild temperature. Kominkova et al. (2017) obtained CdTe QDs by the extracellular biosynthesis by *E. coli*. These CdTeQDs were also prepared by microwave-assisted synthesis. The toxicity of as-obtained QDs was tested using three cell lines, Human Prostate Cancer cells (PC-3), Human Foreskin Fibroblast (HFF), and Breast Cancer cells (MCF-7), and it was observed that the toxicity of biosynthesized QDs to the PC-3 cell lines was almost 35% lower as compared to QDs prepared by the microwave technique.

Qi et al. (2017) used a low-cost hydroxypropyl starch (HPS) to assist sulfate-reducing bacteria (SRB) in the synthesis of ZnS QDs. It was indicated that HPS enhanced the growth of SRB and reduction of sulfate ions into sulfide, which blocked the interaction between sulfide and zinc ions to control the nucleation as well as growth of ZnS QDs. It was observed that average crystal size of as-prepared ZnS QDs decreases from 5.95 to 3.34 nm on increasing the concentration of HPS. There was a blueshift in the absorption peak, which may be due to the quantum confinement effect. The color of photoluminescence spectrum was found to be changed from red to yellow, which is evidence of tunable PL of ZnS QDs. The production of CdS QDs was reported by Ulloa et al. (2018) by acidophilic bacteria, of the *Acidithiobacillus* genus. It was observed that the addition of inorganic phosphate to *A. thiooxidans* ATCC 19703 cultures favored the biosynthesis of CdS QDs in the acidic range (pH 3.5). It was also indicated that phosphate contributes to the biosynthesis of CdS QDs by influencing uptake and tolerance to cadmium.

Yan et al. (2018) produced high-quality CdSe QDs in *Bacillus amyloliquefaciens*. This process has the benefits of short reaction time, high yield, mild synthetic conditions, and good reproducibility. Then as-obtained CdSe QDs were used as a probe for detecting copper(II) ions in blood plasma. It was observed that the protein envelope on the QD surface does not permit interference by others due to selective permeability of the bacterial cell membrane. It was revealed that copper ions in human blood plasma samples could be accurately determined in the range (15.6−18.5 $\mu mol\ L^{-1}$), which is almost similar to results obtained with atomic absorption spectroscopy. Biosynthesis of CdS quantum dots sensitized nanorod arrays of ZnO was reported by Yang et al. (2018). These ZnO nanorod arrays were prepared on FTO using a simple galvanic-cell-based approach. Therefore, these were introduced silanized by (3-aminopropyl)triethoxysilane (APTES) with amino groups, so that Cd^{2+} can be introduced. As-synthesized CdS/ZnO heterostructure was used as photoelectrochemical (PEC)

sensing platform, which exhibited detection sensitivity of 32 CFV m L^{-1} for sulfate-reducing bacteria (SRB). This work can help in the detection of physiological messenger molecules such as hydrogen sulfide.

The role of volatile sulfur compounds was investigated by Gallardo-Benavente et al. (2019) in the biosynthesis of CdS QDs using Antarctic strain *Pseudomonas fragi* GC01. They used different sulfur sources such as sulfite, sulfide, sulfate, thiosulfate, cysteine, and methionine. Intracellular biosynthesis was therefore all sulfur sources except acetylcysteine (Cys) and methionine (Met), where extracellular biosynthesis was there. It was observed that as-synthesized CdSQDs were in the range of 2−16 nm (size). The importance of methane thiol (MeSH) was also confirmed in the biosynthesis of QD. An extracellular biosynthesis of ZnS QDs has been reported by Qi et al. (2019) via a molecular mediation mechanism, which was due to mixed SRB. It was observed that particle size of biogenic ZnS QDs was found to be 6.5 nm. This molecular mediation mechanism was triggered by the peculiar extracellular proteins (Eps) for the higher yield of biosynthesized ZnS QDs. Some other metal sulfide QDs were also prepared, such as CuS, PbS, and CdS.

Bruna et al. (2019) reported biological synthesis of CdS QDs using by polyextremophile halophilic bacteria *Halobacillus* sp. DS2, which was isolated from Uyuni Salt Flat (Bolivia), Atacama salt Flat (Chile), and the Dead Sea (Israel). As-prepared QDs were hexagonal in shape and monodispersed with size ranging between 2 and 5 nm. Abou-Assy et al. (2019) synthesized CdSe QDs using *Providencia vermicola* BGRW. These bacteria had the ability to resist many metals such as silver, cadmium, copper, zinc, nickel, lead, bismuth, and cobalt. It was revealed that biosynthesized CdSe QDs were cubic in shape with a size range of 2−4 nm.

The formation of CdS_xSe_{1-x} QDs has been reported by Tian et al. (2019). These QDs have quantum yield (5.2%) and size of 2.0 ± 0.4 nm. As-prepared QDs (without extra modification) were then used for bioimaging of cancer cells and tumor tissue of mice.

Qi et al. (2019) reported extracellular biosynthesis of ZnS QDs with high yield. As-prepared biogenic ZnS QDs had an average crystallite size of 6.5 nm with better uniformity and greater PL activity than obtained by a chemical route. They have fabricated other QDs such as PbS, CuS, and CdS through this method.

Anthony et al. (2020) synthesized fluorescent carbon quantum dots by nitric acid treatment. They used rice-biryani (processed white rice waste) as a precursor of carbon. As-prepared CQDs were modified further by a two-step process:

1. preparation of reduced-state CQDs (r-CQDs) using borohydride as reductant; and
2. rigidifying with a tripeptide such as glutathione (r-CQDs-GS).

It was observed that QY was enhanced from 5.46% for bare CQDs to 41% for (r-CQDs-GS). As-prepared r-CQDs-GS had an average particle size in the range of $2-5$ nm. It was reported that about 90% cell viability and normal morphology was retained even after treated with r-CQDs-GS concentrations up to $100\,\mu g\,mL^{-1}$. It was reported that r-CQDs-GS could find applications in in vitro/in vivo bioimaging.

Öcal et al. (2020) achieved intracellular preparation of PbS QDs using *Pseudomonas aeruginosa* ATCC 27853. It was revealed that these intracellular biosynthesized PbS QDs had a particle size in the range of 3.47−11.45 nm. As-synthesized PbS QDs showed antibacterial activity against *E. coli*, *Proteus mirabilis*, *Micrococcus luteus*, and *Bacillus cereus*. Órdenes-Aenishanslins et al. (2020) synthesized CdS, Ag_2S, and CdSAg nanocrystals with size less than 15 nm. As-produced CdSAg ternary QDs exhibited high stability, fluorescence, and good quantum yield (36.13%). They could also produce soluble Ag_2S nanoparticles without any traces of Cd. All these three biosynthesized QDs were used as photosensitizers, where CdSAg QDs exhibited the best photovoltaic performance. It was revealed that these nanoparticles are formed in the extracellular space of bacterial cells exposed to cysteine and cadmium chloride.

Sulfate-reducing bacteria are present in anaerobic granular sludge and convert sulfate into sulfide. Jacob et al. (2020) coupled sulfate reduction with precipitation of zinc in ZnS quantum dots. It was reported that biogenic ZnS QDs had an average particle size of 5−7 nm. They determined the bandgap energy of as-synthesized ZnS QDs to be 3.84 eV. These QDs can be used as an effective photocatalyst for the photo-assisted decolorization of Congo red. Ashengroph et al. (2020) developed a method for the biosynthesis of cadmium sulfide quantum dots using a strain of *Pseudomonas chlororaphis*. It was reported that spherical CdS QDs were produced with an average size of 6.7 ± 2.4 nm.

The biosynthetic ternary ZnCdS QDs were prepared by Qi et al. (2021a) by sulfate-reducing bacteria. It was reported that these ternary ZnCdS QDs were monodispersed, spherical in shape, with an average crystallite size as 6.12 nm. The bandgap energy of these QDs were determined to be 2.35−2.72 eV. ZnCdS QDs exhibited remarkable photocatalytic activity for hydrogen evolution ($3.752\,mmol\,h^{-1}\,g^{-1}$) under visible light without using any noble metal cocatalysts. An extracellular biosynthesis of ternary $Zn_xCd_{1-x}S$ QDs has been reported by Qi et al. (2021b) using sulfate-reducing bacteria. It was revealed that these QDs with size of 3.50−4.64 nm could be achieved within half an hour. It was reported that these biogenic QDs exhibited high stability in gastric acid and excellent biocompatibility and biosafety, so that these can enter growing HeLa cells.

Carrasco et al. (2021) analyzed the ability of Antarctic lithobiontic bacterium *Pedobacter* sp. UYP1 in the synthesis of cadmium sulfide quantum dots. Yellow−green and orange−red fluorescent emissions were observed

after 20 and 80 min of synthesis in the presence of UV light, respectively. It was revealed that QDs were obtained with size of 3.07 nm, which were then used as photosensitizers in solar cells. As-fabricated solar cells displayed $V_{oc} = 162$ mV, $J_{sc} = 0.0110$ mA cm^{-2}, and conversion efficiency up to 0.0016%. An anaerobic approach was developed by Xu et al. (2021a) for the biosynthesis of CdS quantum dots (cubic phase and hexagonal phase) using *S. oneidensis* Mr-1. It was reported that as-synthesized hexagonal CdS QDs exhibited high photocatalytic hydrogen evolution (21 mmol g^{-1}CdS h^{-1}).

6.4 Fungi

It was reported by Ahmad et al. (2005) that the synthesis of gold nanoparticles can be controlled in the presence of the fungus *Trichothecium* sp. It was observed that as-prepared gold nanoparticles were spherical, rod-like, and triangular shaped. The synthesis of highly luminescent CdSe quantum dots were reported by Kumar et al. (2007) at room temperature. They used *F. oxysporum*, a fungus incubated with a mixture of $SeCl_4$ and $CdCl_2$. A controllable synthesis of CdSe quantum dots has been reported by Cui et al. (2009) using living yeast cells as a biosynthesizer. These CdSe QDs can be synthesized at 30°C instead of at 300°C, as required in other methods. Apart from this, a control over photoluminescence could be achieved also.

A simple and efficient biosynthesis was reported by Bao et al. (2010b) to prepare biocompatible cadmium telluride quantum dots using yeast cells. It was revealed that as-prepared CdTe QDs are formed via extracellular growth and then an endocytosis pathway. These CdTe QDs are protein-capped with good crystallinity and uniform size (2−3.6 nm). As-prepared QDs are highly soluble in water and exhibit good biocompatibility. The fluorescent biocompatible CdTe QDs can find use in biolabeling and bioimaging applications.

The live yeast cell were used for biosynthesis of CdSe quantum dots by Wang et al. (2010). They prepared seleniumized yeast cells before loading. It was also reported that the on-chip biosynthesis required only 0.5×10^{-4} M concentration of cadmium chloride and only 4−5 h incubation time to obtain the optimum yield of CdSe quantum dots.

Saa et al. (2010) generated CdS quantum dots by enzymatic products. This provided an analytical assay to detect the enzymatic activity of alkaline phosphatase and acetylcholine esterase. The rate of decomposition of sodium thiosulfate to give hydrogen sulfide increases in the presence of thiocholine, which is produced by acetylthiocholine after hydrolysis by acetylcholine esterase. This H_2S in the presence of cadmium sulfate yields CdS quantum dots. This assay was also applied to detect acetylcholine esterase inhibitors.

The cadmium sulfide quantum dots were biosynthesized by Huang et al. (2012) using *Saccharomyces cerevisiae* yeast. It was reported that as-prepared CdS QDs emit blue−green fluorescence under UV light.

Syed and Ahmad (2013) reported fungal-mediated synthesis of CdTe quantum dots using the fungus *F. oxysporum*. They used cadmium chloride and tellurium chloride as the precursor of Cd and Te, respectively. It was observed that these CdTe QDs are highly fluorescent and exhibited antibacterial activity against Gram-positive as well as Gram-negative bacteria. A mechanism-oriented strategy was reported by Li et al. (2013) for controlling the biosynthesis of CdSe quantum dots (fluorescent) through metabolic engineering in yeast cells. It was reported that the glutathione metabolic pathway controlled the intracellular formation of CdSe QDs. It was revealed that yeast cells were homogeneously transformed into efficient cell-factories at the single-cell level, which provides a way to direct the cellular metabolism toward formation of CdSe QDs.

Chen et al. (2014) developed a method for extracellular microbial synthesis of CdSQDs. They used white rot fungus *P. chrysosporium*. This fungus was incubated with a solution of cadmium nitrate tetrahydrate, which turned yellow after 12 h, which indicated that CdSQDs are formed. These QDs exhibited a blue fluorescence (458 nm). The average particle size was calculated to be 2.56 nm with uniform size and good crystallinity. It was revealed that secretion of proteins and cysteine was found to play a dominant role in the stabilization and formation of CdS QDs. Borovaya et al. (2015) reported a reproducible, efficient, and eco−friendly biosynthesis of CdSQDs using mycelium of basidiomycete fungus *P. ostreatus*. The CdSQDs were synthesized using sodium sulfide and cadmium sulfate by incubating *P. ostreatus* mycelium. It was reported that as-prepared quantum dots were spherical in shape ranging between 4 to 5 nm size.

The cadmium selenium quantum dots were synthesized by Wu et al. (2015) using *S. cerevisiae* (ATCC9763). They used sodium selenide and cadmium chloride as the source of selenium and cadmium, respectively. It was reported that the biosynthesized CdSe QDs exhibited much lower cytotoxicity as compared to that obtained with hydrothermally synthesized thioglycolic acid (TGA)-capped CdSe. An efficient method for biosynthesis of CdTe and CdS has been reported by Mareeswari et al. (2016) using fungus *Rhizopus stolonifer*. It was observed that suspension of as-prepared quantum dots exhibited greenish-blue and purple luminescence. It was indicated that these quantum dots are biocompatible in nature. A good contrast in imaging was observed, when these quantum dots were incorporated in human breast adenocarcinoma Michigan Cancer Foundation-7 cell lines.

Polycrystalline ZnS quantum dots were synthesized by Uddandarao (2016) from an endophytic fungus *Aspergillus flavus*. It was revealed that they formed a spherical shape. *A. flavus* was isolated from a medicinal plant *Nothapodytes foetida*. It was proposed that quantum dots synthesized from this fungus may exhibit a great potential in medical and environmental applications. The CdSe QDs were synthesized by Yamaguchi et al. (2016) using *F. oxysporum*. It was reported that CdSe quantum dots were obtained from

the mycelial cells of *F. oxysporum*. It was also revealed that superoxide is accumulated, which may play an important role in reducing Se^{4+} to Se^{2-}; thus, inhibiting the aggregation of CdSe to form nanoparticles.

Jacob et al. (2017) reported the biosynthesis of PbSe QD using marine *Aspergillus terreus*. It was observed that an increase in the total protein content was present in the reaction mixture after biosynthesis. The involvement of metallothioneins (metal binding peptides) and other antioxidant enzymes was confirmed, and it may play an important role in biosynthesis of PbSe QDs. Brooks and Lefebvre (2017) synthesized CdSe quantum dots in the cytoplasm on treating *S. cerevisiae* sequentially with sodium selenite and cadmium chloride. As-prepared CdSe QDs exhibited a yellow fluorescence (540 nm). The presence of glutathione contributed to this biosynthetic process as it inhibited when it was applied after selenite treatment but before the addition of cadmium. It was revealed that by optimizing each aspect the production of CdSe QDs was increased 70% in this case.

Sandoval-Cárdenas et al. (2017) used a sulfur toxic waste, which was recovered after hydrodesulfurization of Mexican oil's sour acid gases. They synthesized cadmium sulfide quantum dots (hydrophilic) via a green method using a fungus, *F. oxysporum*. The mycelia of *F. oxysporum f.* sp. *lycopersici* were incubated with cadmium nitrate (1 mM) and sulfur waste (1% w/v) for 24 h, and then filtered to provide a yellow solution of cadmium sulfide quantum dots. As-obtained CdS QDs were biocompatible, hydrophilic, and stable in nature. It was also revealed that CdS QDs had a wurtzite crystalline structure with size of 6.116 ± 2.111 nm (diameter).

The cadmium selenide QDs were prepared by Tian et al. (2017) in vivo using *Candida utilis* WSH02−08. It was observed that fluorescence properties of these QDs can be turned using different precursor concentrations. It was found that as-synthesized QDs with longer photostable life time and high fluorescence intensity could be obtained by keeping Cd content higher than Se. It was suggested that such synthesized QDs can find application in live-cell imaging without any further modification. A white rot fungus *Trametes versicolor* was used by Qin et al. (2018) for biosynthesis of cadmium sulfide quantum dots. As-obtained cadmium sulfide quantum dots were found to be biocompatible and stable and therefore could have great potential in biological and biomedical applications.

Biosynthesis of CdSe QDs was reported by Shao et al. (2018) using *S. cerevisiae*. The selenocysteine was considered (SeCys) as the primary precursor of selenium in the intracellular biosynthesis of these QDs. It was revealed that the selenomethionine (SeMet)-to-SeCys pathway regulated biosynthesis of CdSe QD. The biosynthesis of ZnS QDs was reported by Jacob et al. (2019a) using the fungus *Aspergillus* sp. It was observed that as-prepared QDs were spherical and crystalline with a mean diameter of 6.3 nm. These ZnS QDs can find numerous applications in the fields of photocatalysis, medical imaging, and biosensing.

Jacob et al. (2019b) biosynthesized ZnS quantum dots from Zn-tolerant *Penicillium* sp. They also revealed that spherical particles of ZnS QDs were obtained with an average diameter of 11.08 nm. As-prepared biogenic ZnS were used for the photodegradation of methylene blue and this degradation efficiency was increased on increasing ZnS nanocatalyst/dye ratio reaching an equilibrium within six hours. These ZnS nanohybrids can find practical utility in the removal of different pollutants released from paper, textile, and dyeing industries. The carbon quantum dots were doped with nitrogen and sulfur (N,S-CDs) by Shi et al. (2019) using fungus fibers. It was reported that N,S-CDs exhibited excellent stability with high quantum yield as well as being water soluble with activity as quenching-based detection and cellular imaging of cancer cells. These QDs can be used as fluorescent probe for efficient, sensitive, and selective probe determination of tetracyclines the linear range of 0.5 to 47.6 μM, with a limit of detection of 15.6 nM. They also prepared test papers using N,S-CDs, which could detect tetracyclines present in aquiculture wastewater in lesser time.

Cao et al. (2020) biosynthesized CdSe QDs using a yeast *Rhodotorula mucilaginosa* PA-1 under aerobic conditions. It was reported that concentration of cadmium ions decides synthesis of CdSeQDs and not the selenium ions. It was found that bio-synthesized CdSe QDs had a narrow size distribution in the range of 3.2 ± 0.4 nm. These QDs exhibited excellent photocatalytic activity in degradation of malachite green in presence of ultraviolet and visible light. The photocatalytic degradation efficiency of malachite green under ultraviolet light was 86.5% after, while it was 94.28% under visible light. A green system was developed by Xu et al. (2020) for the biosynthesis of CdS_xSe_{1-x} QDs by *Phomopsis* sp. XP-8. The QDs were shown to have a CdS0.75Se0.25@oligopeptide transporter structure. It was observed that these QDs were monodispersed with a uniform spherical shape with diameter as 3.22 ± 0.07 nm. These QDs are water soluble and exhibited excellent fluorescence. It was revealed that they can be used as a sensor for detecting chloramphenicol (CAP) in the range of 3.13 to 500 $\mu g\ L^{-1}$ with a limit of detection of 0.89 $\mu g\ L^{-1}$. The detection method was highly selective for CAP with minimal interference from other antibiotics and it was also used successfully to detect CAP in milk samples.

A biosynthesis method to synthesize Ag_2Se QDs was developed by Liu et al. (2021) using *S. cerevisiae*. It was reported that nanoparticles obtained by extracellular purification had a uniform size of 3.9 ± 0.6 nm. These Ag_2Se QDs had good biocompatibility, maybe due to capping by protein. It was observed that the as-synthesized Ag_2Se QDs had lower toxicity and these could be used for in vivo imaging.

Xu et al. (2021a,b) developed a method to biosynthesize $Cd_{0.5}Zn_{0.5}S$ quantum dots using filamentous fungus *Phomopsis* sp. XP-8. It was reported that heterogeneous catalyst functionalized composite mycelium pellets (CMP) exhibited an enhanced visible light degradation activity. The catalytic

activity was also improved as biosorption capacity of CMP increased the contact rate between organic dyes and catalysts. This CMP has high mechanical strength and is easy to separate and recycle; thus the problems of recovery after use and secondary pollution of the environment were avoided.

6.5 Others

Ascencio et al. (2006) obtained small metallic nanoparticles of neodymium via biosynthesis. They could obtain particles of 1−8 nm depending on pH conditions. It was also revealed that smaller clusters were obtained at pH 5, but nanorods were formed at pH 10. Yu et al. (2006) synthesized water-soluble CdSe-ZnS (core-shell) QDs. The g-aminobutyric acid (GABA), an inhibitory transmitter in the central nervous system of mammals, was then bioconjugated to these QDs in the presence of N-hydroxysuccinimide (NHS) and 1-ethyl-3-(3)-dimethylaminopropyl carbodiimide (EDC) to make a fluorescence probe. They could detect GABA binding sites on protoplast membrane of both pollen as well as somatic cells using.

One-pot synthesis of neoglycoconjugates with a reactive thiol group was reported by Babu et al. (2007). Their functionalization with carbohydrates can provide high solubility and stabilization of CdSe − ZnS quantum dots. They used melibiose, lactose, and maltotriose to obtain three different sizes of quantum dots. These sugar-QDs were found to be very selective in the detection of lictin. Huilan et al. (2008) developed a bioinspired technique to synthesize hybrid nanocomposites. It consisted of well-dispersed CdS quantum dots on silk fibroin fibers (SFF). It was observed that biomaterial SFF acts as both a supporting substrate and functional sites for in situ generation of CdSQD. As-prepared CdSQDs/SFF nanocomposites can be used as novel luminescent, photoelectron transfer devices and in photocatalysis.

Manzoor et al. (2009) reported the synthesis of luminescent quantum dots, which were conjugated with a cancer-targeting ligand, folic acid (FA). Doped QDs were prepared by a simple aqueous method at room temperature. It was observed that these QDs are monodispersed with an average size ∼4 nm. The dopants selected were Al^{3+}, Cu^{2+}, Mn^{2+}, and F^{-} and color tunability could be achieved ranging from blue (480 nm) to red (622 nm). It was claimed that nontoxic, Hg-, Pb-, Cd-, Te-, and Se-free luminescent QDs can be used for targeted cancer imaging.

Dong et al. (2009) used l-glutathione (GSH) as a stabilizer for the preparation of CdTe quantum dots in aqueous solution. It was reported that as-prepared QDs were linked to prostate-specific antigen (PSA) for indirect labeling of fixed prostate cancer cells. It was indicated that as-prepared QD-based probes were fluorescent markers and exhibited excellent photostability and spectral properties. These were found to be much better than organic dyes in target detection. It was also suggested that the l-glutathione capped

CdTe had low cytotoxicity as these QDs did not show a detectable effect on cell growth after culturing for three days.

Stürzenbaum et al. (2013) showed that an earthworm's metal detoxification pathway can be used to produce cadmium telluride (CdTe) quantum dots. It was observed that these QDs are water soluble and luminescent in green region. They exposed standard wild-type *Lumbricus rubellus* earthworms to soil that was spiked with cadmium chloride and Na_2TeO_3 salts for 11 days. They isolated luminescent quantum dots from chloragogenous tissues surrounding the gut of the earthworm and used them in live-cell imaging.

Tan et al. (2013) reported that near-infrared fluorescent silver sulfide quantum dots can be synthesized in hepatoma carcinoma cells (HepG2) cancer cells, which is intracellular synthesis. Silver sulfide quantum dots were synthesized by delivering quantum dot precursors into cultured HepG2 cells and these can be used for cell imaging. Zhang et al. (2020) developed CdSe/CdS QDs and used these as a fluorescence sensor for Hg^{2+} detection with high sensitivity in the range of 0.25−100 nM with a limit of detection of 0.01 nM. The as-fabricated sensor exhibited a high selectivity for Hg^{2+} detection of mercuric ion even in the presence of other metal ions and it gave satisfactory results in the case of some samples such as tap water, river water, and landfill.

6.6 Conclusion

Various chemical and physical methods for the synthesis of quantum dots have their own demerits. The majority of them are not green in nature. Biosynthesis methods have certain advantages, such as they are clean, nontoxic, and eco-friendly in nature. In this technique, no hazardous chemicals or reagents are required and harsh conditions are avoided. It is interesting that several nanoparticles (quantum dots) can be easily biosynthesized, which is sometimes not possible by the conventional chemical synthesis. The field of biogenic synthesis is a fairly new and exciting area of research and it has a great potential for further development.

Chapter 7

Microwave-assisted synthesis of quantum dots

Chetna Ameta, Yogeshwari Vyas, Priyanka Chundawat and Dharmendra
Department of Chemistry, M. L. S. University Udaipur, Rajasthan, India

7.1 Introduction

Quantum dot (QD) materials have huge potential for the expansion of novel analytical approaches because of their tiny nanosizes, typically <10 nm for various specific applications (Kumar et al., 2018). Over the last few decades, QDs of different materials have attracted increasing attention in various research fields, for example, as fluorescent biological labels, solar cells, and optoelectronic transistor components, as they have unique size-tunable electronic and optical properties (Kim and Yoon, 2014). Carbon-based QDs, for example, graphene QDs (GQDs), carbon QDs (CQDs), and several types of semiconducting QDs have potential in planning and tuning fluorescent probes (Lim et al., 2015). The zero-dimensional (0D) GQDs generated using top-down methods like electrochemical synthesis, chemical ablation from graphene, oxygen plasma treatment, etc. display a dynamic area of superior interest (Wang et al., 2015a,b). The semiconducting QDs, particularly cadmium telluride (CdTe), cadmium selenide (CdSe), and cadmium sulfide (CdS), have been investigated extensively due to their fluorescent properties in the near-infrared, infrared, and observable spectra (Rodrigues et al., 2017). Lee et al. (2004) reported the production and analysis of size-sensitive and outstanding selective QD structures. Several methods have been employed for synthesizing QD structures using various chemicals; although other synthesis techniques are time-consuming and require costly equipment. Consequently, there is a necessity for a quick, sensitive, simple, and selective process for large-scale production of all types of QDs.

Research is focused on precise experiments for less time-consuming, facile, and fast synthetic methods without losing any heat into the surroundings. Microwave (MW)-aided synthesis provides a facile and fast approach, since it has an alternate energy source and it is exploited widely due to its power of control on volumetric and inner heating of constituents (Agranovich et al., 2017).

Quantum Dots. DOI: https://doi.org/10.1016/B978-0-12-824153-0.00007-0

Recently, more attraction has been paid to MW-assisted generation of inorganic/organic nanostructured materials in different media (gaseous and liquid) and future studies are significant. MWs are largely employed in the synthesis of QD materials, since the interaction is strong with MW rays generating uniform heating and higher heating rates. Thus MW synthesis of metal oxides supported on graphene sheets (Kumar et al., 2014), metal oxide NPs (nanoparticles), and nanostructured carbon materials (Zhang and Liu, 2012) has been studied. Apart from (3D) carbon hybrid metal such as oxide-held graphene and CNTs, activated carbons and carbon nanocapsules were also synthesized (Hu et al., 2012). The MW-assisted path is a quite promising, clean, economic, and low-temperature synthetic route with huge potential. One of the ultimate and notable advantages is that it yields a specific shape and size of QD that depends on the experimental parameters. These MW-assisted synthesized QDs are useful for current and developing technologies and may play a noteworthy role in numerous research areas.

The basic use of MW technology is in the field of transmission of energy or telecommunication by electromagnetic waves. MWs are electromagnetic radiation, ranging between infrared radiation and radiofrequencies. These have frequencies between 300 GHz (1 mm) and 0.3 GHz (1 m). The irradiation technique for rapid heating is based on the principle that materials absorb electromagnetic energy and convert it into heat. The electromagnetic energy transferred from MWs to the irradiated material is believed to occur either through relaxation or resonance. Only contracted frequency windows located at 0.915 and 2.54 GHz are appropriate for MW heating purposes. The MW entails coordinated perpendicular oscillations of magnetic and electric fields. These MW rays are absorbed by materials causing heating, which is known as dielectric heating. This heating is not the same as in the case of conventional form of heating, since energy is transferred in the form of radiation at the surface in MW heating, whereas thermal energy is transported to the material's bulk through conduction.

MW heating is a quick and simple process which is why it is widely employed nowadays in academia and industries for the synthesis of several kinds of QDs. This process results in speedy and even heating (volumetric). Thus, MW is an essential tool in all branches of green synthesis approaches since the time of its origin (Giguere et al., 1986). A wide range of QDs can be synthesized for industrial uses by putting extra efforts into MW-aided synthesis.

7.1.1 Advantages

The MW-assisted production of QDs has numerous advantages compared to conventional routes. The major benefit is the molecular interaction of reagents with an electromagnetic field without direct contact. This method is safe, eco-friendly, with energy proficiency and selectivity, and provides high

yield in a shorter time. All such advantages of MW-assisted synthesis are shown in Fig. 7.1.

7.1.2 Disadvantages

Apart from the many advantages of MW-assisted synthesis, there are some disadvantages or limitations associated with its use in organic synthesis.

1. There is lesser penetration depth in some cases.
2. Metallic substrates or metallic reagents cannot be used for synthesis.
3. Only polar solvents are used, which can interact with the MW.
4. Heating reactions above boiling point of the solvent can generate high pressure, which may cause an explosion.
5. In some cases, the yields are not reproducible because of uneven heating, particularly while using a domestic MW oven.

7.2 Synthesis of core-type quantum dots

Core-type QDs are made up of a single material, basically a metallic chalcogenide like CdTe, CdS, CdSe, PbS, SnO_2, etc. The existing oil-bath heating techniques transfer heat internally from the source (heat), while radiowaves in MW-mediated heating exactly pierce the wall of the vessel to excite polar units like alcohol, water, and fatty acids. Polar molecules absorb this radiation and transform it directly into nuclear motion to convert it into heat. The complete procedure is different from ordinary oil-bath heating since the heat is generated via a native domain by exciting molecules/atoms rather than

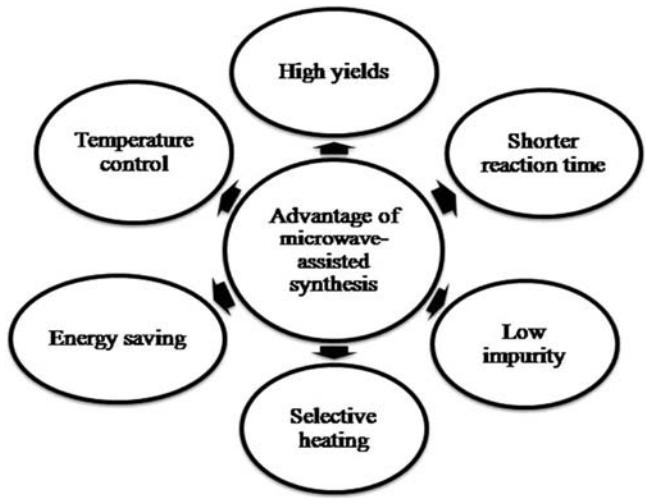

FIGURE 7.1 Advantages of microwave-assisted synthesis.

conduction. Hence, there is no need to drift heat internally by conduction, since all particles are excited simultaneously in the MW field. The use of MW heating in accelerating chemical reactions has fascinated the scientific world extensively in the last few decades. The reducing time of the reaction is not only its merit but it has improved controllability, allowed larger production yields, greener reactions, and reproducibility.

7.2.1 Oxide quantum dots

7.2.1.1 SnO_2 quantum dots

Semiconductor QDs such as tin oxide are attractive materials because of their unique physical and optical properties (Han et al., 2010; Bajorowicz et al., 2018). Tin oxide (SnO_2) has a broad bandgap of 3.6 eV at room temperature. It is a pure n-type semiconductor oxide and it has been widely used in gas sensors, dye-sensitized solar cells (DSSCs), photocatalysts, lithium-ion batteries, and transparent electrodes (Shi and Lin, 2010; Wang et al., 2011a; Wang et al., 2012; Song et al., 2013). Various methods are available for the production of tin oxide such as wet chemical method, laser ablation routes, and MW irradiation technique (Pang et al., 2001; Xiao et al., 2010; Wang et al., 2012, Singh et al., 2012). But most of them require the use of toxic poisonous compounds, critical reaction conditions, and long periods of time. Therefore, there is a challenge for the synthesis of SnO_2 QDs in a fast facile, greener way on an industrial scale. Among several approaches, MW heating has several advantages including better control over the size, lesser reaction time, and even nucleation of precipitates in suspension. Several research teams have utilized MW technique for synthesizing SnO_2 QDs (Xiao et al., 2010; Liu et al., 2013; Bhattacharjee and Ahmaruzzaman, 2015; Begum et al., 2016; Zhu et al., 2016).

Liu et al. (2013) fabricated SnO_2 QDs using MW-irradiation in 10 min. at 150°C with (150 W). These QDs were then used for photocatalytic degradation of methylene blue. The $SnCl_4$ was used as a source of tin. It was revealed that QDs were having particle size of about 3−5 nm. A green synthetic technique was developed for preparation of SnO_2 QDs using MW irradiation. Amino acids (aspartic, glutamic, L-lysine, serine) were used by them. (Bhattacharjee and Ahmaruzzaman, 2015; Begum et al., 2016).

Bhattacharjee and Ahmaruzzaman (2015) obtained globular SnO_2 QDs, when aspartic or glutamic acid (amino acids) and stannous chloride were used as starting materials. It was revealed that diameter of SnO_2 was found to be 1.6 and 2.6 nm for glutamic and aspartic acid, respectively. As-produced QDs were used as an efficient photocatalyst in degradation of two dyes; eosin Y and rose Bengal in presence of solar isolation.

Begum et al. (2016) prepared SnO_2 QDs using L-lysine monohydrate, and sodium dodecyl sulfate (surfactant) under MW exposure. They used these QDs in degradation of humic acid. Then the reaction solution was

given MW treatment. It was revealed that sizes of SnO_2 QDs obtained was 2.3 nm. They used these QDs for degredation of humic acid on solar exposure for 3 h. Begum and Ahmaruzzaman (2018) used *Parkia speciosa* Hassk pods extract in a green economical and less time-consuming process for synthesizing SnO_2 QDs in presence of MW irradiation. As-produced QDs were then used in photodegradation of acid yellow 23. It was reported that QDs also have scavenging activity. It was revealed that average crystallite size of as-obtained SnO_2 QDs was found in the range of 1.5−1.9 nm.

Tin oxide QDs have been prepared by Zhu et al. (2016) using a MW-assisted method. It was reported that SnO_2 QDs (organic component-wrapped) can be synthesized with size 2−4 nm in only 30 s. If these SnO_2 QDs can be obtained by annealing the organic component-wrapped SnO_2 QDs in air at 400°C in 4 h, then QDs with good crystallinity and bigger size (5−10 nm) could be obtained. As-prepared QDs exhibited an excellent sensitivity toward vapors of ethanol as a sensor.

Zhu et al. (2016) reported MW-aided preparation of SnO_2 QDs. They used a mixture of $SnCl_4$, oleic acid (OA), C_2H_5OH, oleylamine (OLA), and H_2O and exposed it to MW (200 W) for different time intervals (0.5−20 min). It was revealed that QDs with diameter of 2−4 nm could be obtained on 0.5 min exposure, but on increasing time to 20 min, QDs are obtained with a larger size of 8−20 nm. Xiao et al. (2010) prepared highly crystalline QDs of SnO_2 under MW irradiation. This involved dissolving $Sn(OtBu)_4$ and 1-butyl-3-methylimidazolium tetrafluoroborate (desiccated) in an inert atmosphere of argon and 1 min exposure to MW irradiation. As-obtained SnO_2 QDs were spherical, monodispersed, and crystalline in nature with size of 4.27 ± 0.67 nm.

A synthetic route was reported by Parthibavarman et al. (2019) for pure and Ag-doped SnO_2 QDs under MW irradiation. It was revealed by TEM images that average particle size of QDs increases on Ag doping. A smaller bandgap (3.54−3.09 eV) was observed on Ag doping. The photocatalytic degradation of rhodamine B and methylene blue was observed in with as-obtained catalyst. A maximum efficiency (97.5%) for degradation of rhodamine B could be achieved in the presence of visible light irradiation. As-obtained Ag−SnO_2 QDs catalyst can be reused and these are stable after even seven cycles.

Mohanta and Ahmaruzzaman (2020) used *Allamanda cathartica* leaf extract for synthesis of SnO_2 QDs. They boiled chopped leaves in water and stannous chloride solution was added dropwise under continuous sonication. On addition of carbon nanoflakes and sonication, a greyish solution was obtained. This solution was exposed to MWs. As-obtained SnO_2 QDs were then used for the removal of bisphenol A.

7.2.1.2 Co_3O_4 quantum dots

Uniform Co_3O_4 octahedrons were obtained by Zhang et al. (2012a,b) via a MW method. Here, various carbon materials were used, which not only acted

as a secondary heater, but also as an agent for directing morphology. A weak ferromagnetic property was found in octahedral Co_3O_4 as-obtained carbon nanotubes using MW.

Zhou et al. (2014) synthesized Co_3O_4 QDs/graphene composites via a MW irradiation method. The crystals of Co_3O_4 were found to be in the size of 3−8 nm. These composites exhibited a high rate capability as well as enhanced cycling performance on use as anode materials for Li-ion batteries. In addition, the well-dispersed Co_3O_4 nanodots and the synergetic effect between graphene nanosheets (conductive and flexible) also gave a better electrochemical performance due to reducing the diffusion pathway of lithium ions and the high surface area.

7.2.1.3 ZnO quantum dots

Lu et al. (2011) synthesized ZnO QDs using zinc sulfate heptahydrate as a precursor. They mixed a Zn precursor with GO. They utilized NaOH for precipitation, where a chocolatey−black suspension was obtained. It was then placed in a MW for half an hour at 150°C. The as-prepared product was filtered and dried at 70°C for a day. This composite was utilized for electrochemical superconductors, and it was proved that ZnO QDs exhibited enhanced activity as compared to GO only.

The Ag and Sn-doped ZnO QDs (ZQDs) were synthesized by Soumya et al. (2018) via a MW-assisted sol−gel method. They used 3-aminopropyl trimethoxy silane as a capping agent. As-obtained ZQDs were then dispersed in methyl methacrylate (MMA) monomer to obtain polymethyl methacrylate (PMMA)/ZQDs. It was observed that doped PMMA/ZQDs hybrid coatings exhibited a blue emission in the presence of UV light. A photochromic dye (spiropyran) was introduced in the doped PMMA/ZQDs hybrids and it displayed photochromic behavior with a red emission. This hybrid can be used in solar radiation control active interface layers.

Rangel-Mendez et al. (2018) reported solvothermal synthesis of C-doped ZnO and TiO_2 hybrid materials under MW irradiation. Titanium isopropoxide, saccharose, and zinc acetate were used as sources of Ti, Zn, and C, respectively. There was a redshift in bandgap of these semiconductors. The TiO_2-C and ZnO-C was obtained (3.02 and 3.13 eV), which was attributed to C-doping effect. It was indicated that these present materials can find application as photoelectrodes for QD-sensitized solar cells (QSSCs).

The nanocomplex was prepared of ZnO QDs by a MW-assisted reaction in the presence of avobenzone (Av) (Asok et al., 2018). It was reported that ZnO QDs can catalyze the formation of highly photostable surface enolate species via an aldol condensation reaction. It was observed that molar absorptivity and photostability was extended beyond the UV-A filtering range, and therefore it can provide a visible emission color matching human skin.

7.2.1.4 WO_3 quantum dots

Le Houx et al. (2009) carried out the synthesis of WO_3 QDs by both MW and conventional heating and compared the results. It was reported that particles obtained with MW-heating were more suitable compared to conventional heating or routine preparation. There have greater specific surfaces and particle size, ranging between 5 and 30 nm.

Wang et al. (2015a,b) fabricated tungsten oxide QDs using a one-pot MW-assisted method. It was reported that as-obtained WO_3 QDs have a size ranging from 2 to 3 nm. These WO_3 QDs exhibited significant photonic/thermal stabilities. It was interesting to note that a colorless aqueous suspension of WO_3 QDs turned blue in the presence of sunlight in 10 s indicating its photochromic behavior. This type of behavior was attributed to surface oxygen vacancies as well as exposed reactive sites of ultrafine WO_3 QDs.

7.2.1.5 SiO_2 quantum dots

Mao et al. (2014) prepared N-acetyl-L-cysteine-stabilized CdTe/CdS@ZnS−SiO_2 QDs red-luminescent under MW irradiation. The Stober method was used for coating silica on CdTe/CdS QDs. The as-compared QDs exhibited high photoluminescence (PL), low biotoxicity, and superoptical stability. They utilized the QDs in a low-power surface-mounted and a high-power device.

7.2.1.6 CeO_2 quantum dots

Lehnen et al. (2014) prepared CeO_2 QDs via MW-solvothermal synthesis of N-methylpyrrolidone. The synthesis procedure involves a MW reactor at 50 W at 150°C and 1.5 bar for 5−15 min. It was observed that crystallinity of CeO_2 QDs was improved, when reaction time was kept at 15 min. The product was collected after centrifugation and purification. The average size of CeO_2 QDs was found to be 4.3 nm. He et al. (2017) synthesized CeO_2 QDs using a MW-assisted method. A mixture of OLA and cerium (III) nitrate hexahydrate was first heated for half an hour at 80°C under vacuum and then placed in a MW oven at 180°C. These QDs were cooled down and washed and were then kept dispersed in tetrahydrofuran and stored at −20°C.

Soren et al. (2015) fabricated CeO_2 QDs via MW-assisted synthesis. In MW-hydrothermal synthesis, autoclave cerric ammonium nitrate and NaOH were used in the ratio (1:6) with water and pH was adjusted to 10 and exposed to MW irradiation, while in MW solvothermal synthesis, cerric ammonium nitrate and 1,4-butanediol were used and pH was maintained at 6. This mixture was then exposed to MW rays for 20 min. It was revealed that MW-mediated solvothermal method could yield less agglomerated and smaller size QDs (5−10 nm), whereas larger NPs size (15−20 nm) was produced on using the MW-mediated hydrothermal technique.

7.2.1.7 TiO_2 quantum dots

Alves et al. (2018) reported the synthesis of graphene-TiO_2 QDs via the MW-oleothermal method. They mixed OLA, graphene oxide (GO), OA, 98% titanium propoxide, and Triton-X under magnetic stirring at ambient conditions, which was followed by the oleothermal method and sonicated for 15 min in the presence of MW radiation. It was observed that the diameter of synthesized QDs was found to be around 3 nm.

7.2.1.8 MoO_2 quantum dots

Cao et al. (2020) fabricated phosphorus and nitrogen codoped MoOx QDs (N,P-MoOx QDs) using MW-assisted method. The $H_3P(Mo_3O_{10})_4.xH_2O$, glutathione (GSH), and ultrapure water were mixed, stirred, and sonicated for 5 min. The mixture was placed under MW radiation in an autoclave for 8 min after adding ammonium solution.

7.2.1.9 CuO quantum dots

The CuO QDs were prepared by Bekru et al. (2021) using the MW-assisted modified method. They used copper acetate as the source of copper extract of leaves of *Cordia africana* Lam. Then, the mixture was irradiated by MWs (1000 W) for 9 min. A brown precipitate of CuO QDs was obtained and thius were utilized in the reduction of 4-nitrophenols. Felix et al. (2015) also synthesized CuO QDs using a MW-assisted method. An average size of CuO QDs was found to be about 4 nm. As-prepared CuO QDs exhibited high sensitivity for electrochemical sensing as compared to their microcounterparts.

7.2.2 Sulfide quantum dots

7.2.2.1 CdS quantum dots

Alehdaghi et al. (2020) obtained CdS QDs and examined the consequence of gamma radiation on their chemical and physical properties. These QDs were prepared in less than 10 min under MW radiation. They studied the PL and transmittance characteristics of CdS QDs. The size of CdS QDs was confirmed as 3−4 nm from TEM analysis. It was revealed that degradation of PL of QDs was found to be inversely dependent on concentration. The redshift was found to be more with a lower size of QDs. It was claimed that as-prepared CdS QDs may be promising material for use as a gamma dosimeter.

Zheng et al. (2010) synthesized mesoporous CdS QDs via a simple and cost-effective method (in situ conditions). They used OA. A soft template for MW treatment was used instead of sintering, because the mesostructure is destructed under this condition. It was observed that on adding Na_2S, the color of the gel changed to yellow. It was revealed that both these samples of CdS QDs (naturally evaporated and MW irradiated) had a size of 3−4 nm.

Fregnaux et al. (2013) made a comparative study of CdS formation via single-source precursor methodology (SSPM) and MW synthetic route (MWSR). The average particle size of QDs ranged between 4.5−5.2 and 2.8−4.5 nm when prepared with MWSR and SSPM techniques, respectively. It was observed that CdS QDs prepared by MWSR had a cubic structure, while SSPM afforded QDs with hexagonal structure. It was also concluded that there is better optical quality in MWSR-grown QDs. It was revealed that a stable behavior of QDs was due to the absence of S vacancies when treated in air.

Alehdaghi et al. (2014) synthesized CdS QDS by dissolving both in S as well as Cd precursor deionized water, followed by the addition of TGA. It turned into a milky solution, which was made transparent by adding ammonia. This solution was then exposed to MWs for various time intervals to afford QDs of different sizes. Liu et al. (2014) synthesized CdS QDs using the MW-assisted chemical bath deposition technique. They utilized thiourea and cadmium nitrate as precursor solutions. Then TiO_2 film was introduced containing a precursor solution, and it was placed under MW exposure for 20 min. The crystal size of as-obtained QDs was found to be 5 nm.

Butova et al. (2017) prepared CdS QDs via a MW hydrothermal method in 5 min. They stabilized these QDs with 4,4'-bipyridine and dioctyl sodium sulfosuccinate. They also investigated the impact of different capping mediators on particle shape, size distribution, and properties. They used cadmium nitrate as precursors. It was revealed that Cds QDs were about 5 nm in size. It was revealed that smaller particle size was obtained when 4, 4'- bipyridine was used as a stabilizer.

The CdS QDs were also prepared by Radzi et al. (2020). They used a mixture of solutions of $C_{10}H_{17}N_3O_6S$ (GSH), and $CdCl_2$, and added Na_2S to these drop wise. This mixture was heated at 150°C in a MW reactor for 1 min only. It was revealed that the average diameter of CdsQDs produced was found to be 5.8 ± 0.3 nm. These QDs were embedded into PVA (polyvinyl alcohol) (matrix film) and were used in an absorber in Q-switches.

7.2.2.2 ZnS quantum dots

ZnS is a significant type of II-VI semiconductor QD because of its luminous properties. ZnS crystals are in two phases: hexagonal phase (wurtzite form) and cubic phase (zinc blende, sphalerite). The bandgap of ZnS falls in the range of 3.68−3.80 eV. It was observed that the cubic phase of ZnS is more stable at lower temperatures, but at higher temperatures it transforms to its wurtzite phase. MW-irradiation is an efficient and eco-friendly method as it provides high-purity particles, a greater yield of QDs, requires a simple reaction medium, has a lesser reaction time, and is an economically visible route. Here, capping agents may play an important role in enhancing the properties of QDs, such as luminescent nature, stability, and morphology, which prevents their agglomeration.

Ayodhya and Veerabhadram (2018) prepared ZnS QDs (undoped and doped) under MW irradiation. They used Rh^{3+}, Pd^{2+}, and Zr^{2+} as dopant materials. The precursor solutions (zinc acetate and sodium sulfide) were prepared in water. The white colored ZnS was obtained on MW irradiation (1000 W) on exposure of a mixture of precursor solutions for 10 min. Undoped and doped ZnS QDs were prepared in the absence and presence of dopant. The structure of ZnS QDs was cubic and the size of these as-prepared QDs ranged between 2 and 10 nm. It was observed that both these ZnS QDs exhibited superior fluorescence quenching with the cysteine molecules and these can be used as an efficient fluorescent material for quenching and binding practices.

Mathew et al. (2010) fabricated folic acid (FA) conjugated carboxymethyl chitosan (CMC), which was coordinated to Mn-doped ZnS QD (FA−CMC−ZnS:Mn) nanoparticles. The zinc acetate, manganese sulfate, and sodium sulfide were used as precursors of zinc, manganese, and sulfur, respectively. A white colloid was obtained, which was treated under MW irradiation for 1 min. These as-obtained QDs were utilized for monitoring, targeting drug delivery, and imaging of breast cancer cells.

Shahid et al. (2012) reported MW-assisted fabrication of ZnS QDs (wurtzite). The size of as-obtained QDs was 3 nm. Saravanan et al. (2012) made a comparison between MW and conventional techniques for preparation of ZnS QDs. They used sodium sulfide and zinc acetate as the source of sulfur and zinc, respectively. It was revealed that the size of QDs prepared using the MW method was very small (diameter $\sim$3 nm). It was revealed that these QDs were almost 30 times smaller than those produced by the conventional method. The bandgap of bulk ZnS was 3.67 eV, which was found to increase to 3.9 eV on MW treatment.

Zhu et al. (2014) synthesized Mn-ZnS QDs via MW-assisted technique. Zinc nitrate and manganese chloride were selected as the source of zinc and manganese, respectively. A solution of sodium sulfide was added to sodium palmitate solution. The mixture was kept under MW irradiation (260 W) for 35 min. It was revealed that the average particle size of Mn−ZnS QDs was found to be 4.2 nm as evident from HRTEM images.

He et al. (2019) reported a facile method of producing copper-doped ZnS QDs (ZnS:Cu QDs) using MW irradiation. They used 3-mercaptopropionic acid as a source of sulfide as well as a stabilizer. The copper sulfate and zinc acetate were used as precursor of copper and zinc, respectively. It was observed that the size of QDs increased very little from 4.1 to 4.7 nm on increasing the time from 10 min to 2 h. As-prepared ZnS:Cu QDs were utilized in the lighting device. It was interesting to note that as the time of exposure was increased, the emission color of ZnS:Cu QDs changed from blue → green → yellow → orange−red.

Shaheen et al. (2020) synthesized zinc sulfide QDs by MW route. They found 1-dodecyl-3-ethylimidazolium bromide, surface active ionic liquid

suitable as a capping agent because of its amphiphilic nature, superior aggregation property, and eco-friendly behavior. As-obtained QDs were found to be thermally stable with a size of 3.03 nm (diameter). They also reported their application as a sensor for ascorbic acid. The fluorescence property of QDs was attributed to high sensitivity, low cost, and ease.

7.2.2.3 PbS quantum dots

He et al. (2012) prepared PbS QDs. They used lead chloride and thioacetamide as the source of lead and sulfur, respectively, and 3-mercaptopropionic acid as a stabilizer. The reaction mixture was exposed to MW irradiation (960 W) only for 40 s. As-obtained PbS QDs solution was light gray-green in color and the particle size of PbS QDs was 5 nm in diameter.

Liu et al. (2019) embedded $Pb(DMDC)_2$ with PbS QDs by reducing dimethyl dithiocarbamate (DMDC) in ethanol. It was further treated by MW and ultrasonic−irradiation (200 W). The color of the solution was finally changed from colorless to black, which indicates the formation of PbS QDs.

Molaei et al. (2020) prepared PbS QDs in water using LG as a stabilizer and for distribution in the blood transmission. They mixed lead acetate and LG before the treatment by MW irradiation for 30 s after addition of sodium sulfide.

7.2.2.4 CuS quantum dots

Nethravathi et al. (2019) utilized MW irradiation in the synthesis of CuS QDs. They used sonication before MW exposure. They used copper hydroxydodecylsulfate and thiourea as a precursor of copper and sulfur, respectively. The resulting mixture was treated with MW (800 W) for 5 min. Black colored CuS QDs were obtained. These QDs were used for photocatalytic degradation of methylene blue, methyl orange, and 4-chlorophenol in sunlight. They were separated via centrifugation and purified by washing and then dried.

CuS QDs were synthesized by Chaudhary et al. (2014) in very high yield in MWs in 2 min. The particle size of as-obtained QDs was in the range of 2−3 nm. These CuS QDs were used as a catalyst in Biginelli reaction under solvent-free conditions affording dihydropyrimidinones in excellent yields. This catalyst can be recovered and reused for a number of cycles. Malankowska et al. (2020) obtained CuS_2 QDs under MW irradiation. The size of CuS_2 QDs was found to be 2−3 nm. The efficiency of CuS_2 QDs and QDs-sensitized TiO_2 composites was evaluated in the degradation of toluene under LED irradiation.

7.2.2.5 AgS quantum dots

Mir et al. (2018a) prepared silver indium sulfide (AIS@ZnS) core−shell QDs via a MW-assisted method. They used a stabilizer GSH. The appearance of a

golden color indicates the formation of silver−indium sulfide QDs. An average diameter of core and core−shell nanocrystals diameter was found to be 2.5−3.25 nm, with corresponding bandgap and yield of 2.3−3.1 and 2.4−3.5 eV and 26% and 49%, respectively. The core−shell QDs display color-tunable production in the noticeable region (500−600 nm) by varying the Ag:In molar ratio.

Mirahmadi et al. (2020) synthesized Ag_2S and Ag_2S@ZnS QDs via a MW method. These as-prepared Ag_2S and Ag_2S@ZnS QDs were used as cosensitizers in the fabrication of QDs solar cells (QDSCs), where an enhancement of cell efficiency (3%) and short current density (12.5 mA cm^{-2}) could be achieved.

7.2.3 Selenide quantum dots

7.2.3.1 CdSe quantum dots

Attempts were made to produce CdSe QDs (Peng and Peng, 2001; Li et al., 2003). Here, organic phosphine and cadmium oxide/organometallic precursors were utilized as ligand and crude material in a temperature range of 250°C−350°C. As-produced CdSe NPs were found to be soluble only in nonpolar solvents unless some surface modification is made. It has been observed that PL of CdSe QD was reduced, if any surface alteration is being made since it is hypersensitive to the surface characteristics (Nazzal et al., 2003). So, it is necessary to develop a directly water-soluble production route. The commercial preparation of CdSe has its own limitations, such as the use of poisonous organic phosphines, elevated temperature, and costs linked with oxygen-free equipment. Therefore, there is a necessity for a pathway that is greener, with harmless chemicals, lower temperatures, and fast reaction method. The CdSe QDs can be utilized in photovoltaic biomedical engineering lasers and solar drive cells (Peng, 2002; Pradhan and Peng, 2007). The MW-assisted heating method is easy as well as there is swift control of the reaction.

Wang et al. (2004) were able to produce fairly stable CdSe NPs utilizing MW heating of 1,1-dimethylselenourea and cadmium perchlorate (in the presence of citrate). They used MW (900 W) for preparation of CdSe QDs. Zhu et al. (2009) reported MW-assisted synthesis of CdSe QDs. They used OA as a nonphosphine ligand. Cadmium oxide and diesel were mixed with OA, followed by the addition of selenium powder in diesel and glycerol. This mixture was exposed to MW (170 W) for 2 min.

A rapid MW-assisted process was developed by Zhang et al. (2012a,b) to produce protein-conjugated CdSe QDs. They used ribonuclease A (RNase A) as a template for the generation of CdSe clusters. These clusters were found to be less toxic and exhibited excellent stability. The MW exposure was required for 5 min. It was revealed that the shape of QDs was regular

spherical with an average size of 5 nm. Moghaddam et al. (2012) reported a one-pot protocol for the synthesis of monodispersed colloidal CdSe QDs with the help of MW radiation. Here, 1-octadecene (ODE) played a dual role of a solvent and reducing agent. They observed that CdSe QDs can be fabricated with different sources of cadmium, where their particle sizes ranged between 0.5 and 4 nm.

Xuan et al. (2013) prepared CdSe QDs via MW-assisted synthesis for use in white light-emitting diodes with outstanding color rendering features. It was reported that size and optical properties of these QDs can be modified by changing the MW power growth temperature as well as reaction interval and molar ratio of Cd^{2+} with Se. It was revealed that as-produced QDs exhibited spherical shapes with a diameter of 4.8 nm.

CdSe QDs were prepared by Mehrjoo et al. (2017) using the MW-assisted method. They used TGA as a capping agent and $CdSO_4$ and Na_2SeO_3 as precursors. The MW (720 W) was used for 90 s for their synthesis. It was reported that as-produced CdSe QDs were found to be 5 nm in size. Then, these QDs were used for the degradation of methyl orange.

Abolghasemi et al. (2019) also used an MW-assisted method for the production of CdSe QDs. They used CdO and Se powder as precursors. It was observed that the particle size of CdSe QDs varied in the range of 5−7 nm. It was indicated that as-prepared QDs can be used in solar cells (as a sensitizer) with an efficiency of 3.57%.

7.2.4 Telluride quantum dots

7.2.4.1 ZnTe quantum dots

Alvand et al. (2019) synthesized zinc telluride QDs (ZnTe QDs) using the aqueous extract of *Ficus johannis*. Ultrasonic as well as MW techniques were applied for the preparation of plant extracts, which can be utilized as stabilizing precursors during the synthesis of ZnTe QDs. The nanoparticles of ZnTe QDs had an average size of 8 nm. It was reported that as-prepared QDs produced antimicrobial, antifungal, and antioxidant properties.

A series of $Zn_{1-x}Pm_xTe$ QDs was synthesized by Al-Harthi et al. (2021) via 4,4-bis-*N*-1-naphyl-*N*-phenylaminobiphenyl through MW-assisted method. These QDs showed remarkable optoelectronic properties. It was observed that the bandgap of ZnTe QDs was reduced from 3.06 to 2.8 eV in the presence of promethium ions and particle size was increased from 1.4 to 4.3 nm. The inclusion of promethium ions in these QDs ions was found to be responsible for tuning the color of QDs in the visible region. It was suggested that as-prepared $Zn_{1-x}Pm_xTe$ QDs can find potential application in photovoltaic devices.

Du et al. (2012) developed a MW-assisted method for synthesis of GSH-capped $Zn_{1-x}Cd_xTe$ alloyed QDs. They used Na_2TeO_3 as a source

of tellurium. The photoluminescent quantum yield of as-synthesized alloyed QDs could reach up to 90%. As-prepared $Zn_{1-x}Cd_xTe$ alloyed QDs have a potential as biological fluorescent labels in different biological applications.

Zhan et al. (2013) prepared CdSe QDs covered by double-shells of CdZnS and CdS using a one-pot MW-assisted route. It was reported that as-prepared CdSe/CdS/CdZnS core−shell−shell (CSS) QDs exhibited high crystallinity and high-fluorescence quantum yield of 90%. As-obtained QDs also displayed stability toward light, acid, and oxidation. These CSS particles have an average size of QDs around 3.2 nm. It was revealed that as-prepared QDs can find a potential for fluorescent QDs-based biological applications.

Kim and Kim (2016) synthesized CdZnTe QDs using MW irradiation in aqueous solution. They used 3-mercaptopropionic acid as a stabilizer. Zinc nitrate, cadmium nitrate, and NaHTe were used as precursors of Zn, Cd, and Te, respectively. It was reported that absorbance spectra and PL of these QDs exhibited a redshift.

7.2.4.2 CdTe quantum dots

CdTe has found varied applications like sensors, photovoltaic devices, bioimaging, and biolabeling because of its higher quantum efficiency. These are synthesized via aqueous and nonaqueous methods such as thermal breakdown, solvothermal, MW, and sonochemical treatment routes. MW irradiation has several advantages over other methods.

He et al. (2006) synthesized CdTe QDs with a MW-assisted method. They used NaHTe and $CdCl_2$ as precursors solutions of Te and Cd respectively. The 3-mercaptopropionic acid was utilized as a stabilizer. Kanwal et al. (2010) also used this method with slight modifications. Here, mercaptosuccinic acid was used as a stabilizer. It was observed that dimensions of CdTe QDs can be changed by simply changing the time intervals of heating. It was also revealed by Wang et al. (2008) that production of CdTe QDs with mercap to succinic acid as a stabilizer consumed less time and as-obtained QDs exhibited durable PL with high quantum yield.

Kominkova et al. (2017) prepared CdTe QDs by MW treatment. They used Na_2TeO_3 as the precursor of tellurium. The reaction mixture was heated under MW (300 W) for 10 min. Molaei et al. (2015) also prepared CdTe QDs. They used $CdSO_4$ and NaHTe as the precursor of Cd and Te, respectively. Here, TGA was used as a capping agent. In the final stage, a yellow-orange solution was obtained, which was placed under MW (720 W) for various time periods. The diameter of as-obtained CdTe QDs was found to be 2.5 nm.

Singh et al. (2017) fabricated CdTe QDs using $CdCl_2$ and TeO_2 as the precursor of Cd and Te, respectively. The MPA was also mixed in this solution in 100 mL milli-Q water. Then this mixture was exposed to MW irradiation

(300 W). It was observed that spherical QDs were obtained in a cubic structure and an average diameter of 2.5 nm was evident from XRD and TEM analysis. A redshift was also found with a change in particle size on increasing the time of exposure. These as-fabricated CdTe QDs were then used in latent fingerprinting and it was claimed that only a few seconds were needed to detect fingermarks under UV treatment.

Singh et al. (2017) used the one-step MW irradiation method for the synthesis of capped CdTe QDs. They used 3-mercaptopropionic acid as capping agent. The TeO_2 was used as the source of tellurium in place of commonly used Te powder, Na_2TeO_3, or Al_2TeO_3. The average particle size of the QDs was found in the range of 2−3 nm. These capped CdTe QDs can be used for latent fingerprinting.

MW irradiation route was developed by Duan et al. (2009) for the synthesis of CdTe QDs. The 3-mercaptopropionic acid was used as stabilizer. It was revealed that as-obtained CdTe QDs could be used as fluorescent probes for detect ion of mercuric ions in aqueous solution with a detection limit of 2.7×10^{-9} mol L^{-1}.

Ribeiro et al. (2017) reported a MW-assisted synthesis of CdTe QDs. They used three different ligands (2-mercaptoethanesulfonate, 3-mercaptopropionic acid, and L-GSH reduced) as capping agents. They could achieve CdTe QDs with quantum yield of ∼60%. A simple synthesis of CdTe QDs has been reported by Chen et al. (2015a) under MW irradiation. They used GSH as a modifier. It was revealed that as-prepared CdTe/CdS QDs were more dispersible and exhibited higher fluorescence intensity.

Dong and Ren (2012) developed a MW-assisted method for synthesis of CdTe QDs. They used long-chain thiols-mercaptoundecanoic acid (MUA) as surface ligand. It was revealed that as-obtained MUA-coated CdTe QDs were having have good stability, small diameter, long lifetime, and high luminescence. It was also revealed that these MUA-coated QDs could be used for HeLa cell imaging.

A MW-assisted synthesis of water-soluble cadmium telluride QDs was reported by Alibolandi et al. (2014). They used sodium tellurite and cadmium chloride as the source of Te and Cd, respectively. The mercaptosuccinic acid was used as a capping agent, CdTe nanocrystals with different colors ranging from blue to orange were obtained in less than one hour. It was revealed that qualified AS1411-aptamer-conjugated QDs exhibited that these can be used as excellent nanoprobes for targeting of cancer and molecular imaging. Bichpuria and Oudhia (2016) prepared GSH capped CdTe QDs (GSH-CdTe QDs) using a MW assisted wet chemical method. It was observed that high loss tangents and high boiling point were effective in controlling the size dispersion of QDs in MW-assisted synthesis.

7.2.5 Other quantum dots

A MW-assisted synthesis of silver indium sulfide (AIS) and AgInS@ZnS (AIS@ZnS) core−shell QDs was reported by Mir et al. (2018b). They used

GSH as a stabilizing agent. An average particle size of 2.5 and 3.25 nm was obtained for core and core−shell nanocrystals with bandgap as 2.3−3.1 and 2.4−3.5 eV, respectively. It was revealed that AIS@ZnS particles can easily penetrate the cells. It was suggested that as-obtained QDs have the potential to be used as antifungal and photodynamic agents as well as in high contrast cell imaging.

Fitzmorris et al. (2015) synthesized $CuInS_2$ QD cores using a MW-assisted reaction. It was indicated that the $CuInS_2$/ZnS (core/shell) QDs were ~98% ZnS, while In and Cu were present in lower concentrations. It was reported that PL stability was improved with ZnS shell and PL down conversion efficiency of ~65% was there on using a blue LED source.

Hong et al. (2015) synthesized $CuInS_2$/ZnS (core/shell) QDs via one-pot MW irradiation. It was observed that as-prepared QDs exhibited emission ranging from the red to NIR. The as-prepared CIS/ZnS QDs not only possess a high PLQY (56%) but also exhibit a large Stokes shift. It was revealed that these QDs can convert near UV and blue light in the Si solar cell with lower sensitivity to red and NIR light, where these solar cell has relatively higher sensitivity. Especially when they were first embedded into a PMMA transparent matrix to form a composite film as a luminescent downshifting layer for Si solar cell, the photoelectric conversion efficiency of the cell shows a marked enhancement by spectral downshifting as compared to the bare glass substrate, and the maximum achieved is 16.21%.

A green MW-assisted synthesis of $CuInS_2$ (CIS) and $CuInS_2$@ZnS core−shell QDs (CIS@ZnS) was reported by Mir et al. (2018b). They also used GSH as a stabilizer. The average particle size of CIS and CIS@ZnS was found to be 2.9 and 3.5 nm, respectively. It was observed that core−shell QDs exhibited better binding with lysozyme as compared to core structures.

Yang et al. (2012) synthesized Cu-doped ternary ZnCdS QDs (ZnCdS:Cu QDs) using a MW-assisted method in aqueous solution. They prepared samples at different Cd concentrations. These ternary QDs were found to be dispersible in water solution. It was observed that their PL peak was red-shifted and quantum yield of these QDs could reach as high as 12% depending on the doping concentration of Cu. It was concluded that as-fabricated ZnCdS:Cu ternary QDs may find application in fields such as bioimaging, sensing, and light-emitting diodes.

7.3 Synthesis of core−shell quantum dots

Core−shell QDs (CSQDs) have a solid core that is encapsulated within a second QDs material with an upper bandgap. Such hybrid particles have an enhanced quantum yield over QDs of single material. The II−VI compounds are useful for many purposes such as sensors, solar cells, probes, LEDs, photocatalysts, etc. QDs have a very high surface-to-volume ratio (around 80%) of atoms. They can provide various interesting properties. The CdSe

QDs have been exclusively investigated, which can be further improved by having a shell of ZnS as its bandgap is high compared to CdSe. The CSQDs can be categorized depending on the position of conduction and valence bands in the semiconductor materials. If the core has a larger bandgap as compared to the shell, then these are known as type I or conversely (inverse type I). On the other hand, if the conduction band or valence band of the core is placed within the bandgap of the shell, then these are classified as type II, CS QDs.

7.3.1 Type I CS quantum dots

Ziegler et al. (2007) used a green method to synthesize a ZnS shell over a CdSe core using MW irradiation. The proximity of core and shell was examined by the thiophenol test. Formation of the shell was started by MW exposure (within 30 s at 800 W). The mixture was then stirred for a minute and exposed to MWs (600 W).

Duran et al. (2014) reported a rapid method for the synthesis of water-soluble CdSe/ZnS QDs using MW technique. They used L-cysteine, cysteamine, and 3-MPA as thiol ligands. It was found that CdSe core was covered by ZnS shell. This method also increased the crystallinity of ZnS (shell).

Molaei et al. (2016) prepared CdSe/CdS CSQDs by an MW-assisted method in a single pot. They used two methods: MW irradiation (720 W) and chemical reaction (between NaHSe, $CdSO_4$, and TGA as capping ligand). It was observed that a CdS shell was developed on the CdSe. The formation of CdSe/CdS core−shell QDs is given as:

$$\mathbf{CdSO_4} + \mathrm{TGA} \xrightarrow[\mathbf{MW}]{\mathbf{NaHSe}} \mathbf{CdSeQDs}$$

$$\mathrm{CdSeQDs} + \mathbf{CdSO_4} \xrightarrow[\mathbf{MW}]{\mathbf{Na_2S_2O_3}} \mathrm{CdSe/CdS}\ \ \mathbf{CS\ \ QDs}$$

7.3.2 Inverse type I CS quantum dots

Shen et al. (2012) reported MW-assisted fabrication of highly luminescent cadmium selenide tellurium@zinc sulfide-silicon dioxide (CdSeTe@ZnS-SiO_2) QDs, which are helpful in detecting Cu(II) ions. These QDs were prepared with ZnS-like clusters, which were incorporated into the shell of SiO_2 in the presence of MW irradiation. The Zn^{2+} and GSH were utilized as precursors for ZnS. An average diameter of CdSeTe QDs was found to be 3.9 nm. It was reported that as-prepared CSS QDs have high luminescence and water solubility.

Ma et al. (2013) utilized a MW irradiation oven for the synthesis of GSH-capped ZnSe/ZnS core−shell QDs. Zinc acetate and KHSe were used as the source of zinc and selenium, respectively. The GSH was utilized as a capping agent. The molar ratio of Zn:GSH:KHSe was kept as 1:1.6:0.1 for better results.

Ebrahimi and Souri (2020) synthesized ZnSe:Cu@ZnS core−shell QDs using a MW-assisted colloidal method. It required 6 min of exposure to MW irradiation. It involves ZnSe and ZnSe:Cu semiconducting NCs in aqueous medium. The thioglycolic acid was used as a capping agent so that no agglomeration occurred. The NaHSe was prepared by reaction of Se with $NaBH_4$.

7.3.3 Type II CS quantum dots

Sai and Kong (2011) synthesized crystalline, water-soluble CS QDs (CdTe/CdSe QDs) via a MW technique. These are type II QDs. The solution of cadmium chloride (N_2-saturated) and NaHTe in the presence of MPA was exposed to MW irradiation for core formation (CdTe) for 2 min. It was reported that as-prepared QDs were monodispersed with a crystalline nature and size of 2 nm.

The MW-assisted technique was used by Chen et al. (2015b) to synthesize GSH conjugated CdTe (core)/CdSe (shell) QDs (CS QDs). The core QDs was prepared using cadmium chloride and MPA solutions. They used NaHTe solution as a source of Te. The resultant solution was exposed to MW irradiation for 2 min. The NaHSe solution was used as a precursor for selenium. Then, a solution of CdTe core QDs was added and exposed to MW for 20 min.

7.3.4 Inverse Type II CS quantum dots

Ren et al. (2013) produced PbS/CdS CS QDs via MW-assisted cation interchange method. A mixture of CdO, 1-ODE, and OA was heated in an oil bath until color disappeared. Then PbS QDs were injected using a syringe and the resultant solution was heated under MW (300 W) irradiation. It was observed that CS QDs were monodispersed with QY of 57%, which was almost 1.4 times more in the case of MW-assisted preparation as compared to the oil bath method.

7.3.5 Core−shell−shell quantum dots

The CSS (CdTe/CdS/ZnS) QDs were synthesized by He et al. (2008) under MW irradiation. As-prepared CSS QDs may be found useful as fluorescent probes in biological applications as these have good spectral properties, good biocompatibility, aqueous dispersibility, and excellent photostability (Fig. 7.2).

Wang et al. (2013) synthesized CdTe/CdS/ZnS QDs under MW irradiation for 10 min. The average particle size of CdTe/CdS/ZnS QDs was found to be >8 nm. It was reported that as-prepared CdTe/CdS/ZnS CSS QDs showed a maximum emission wavelength of 780 nm. Their synthesis is diagrammatically presented in Fig. 7.3.

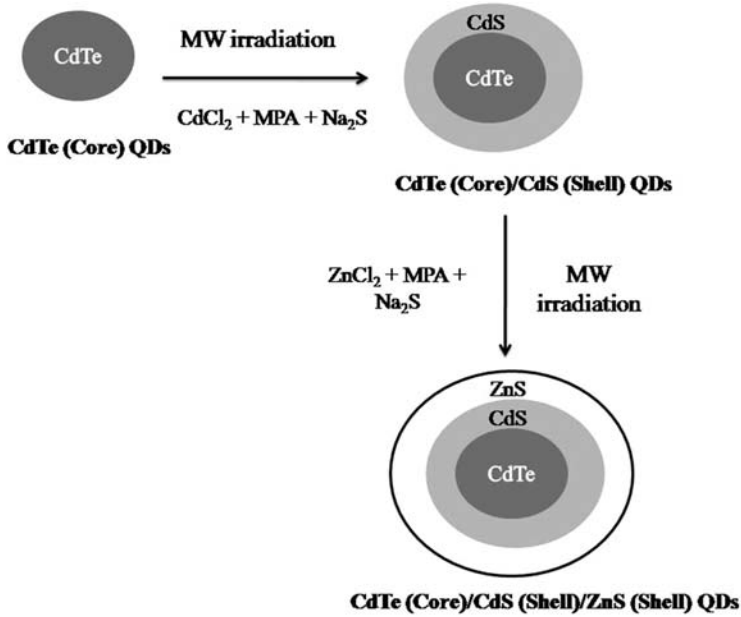

FIGURE 7.2 Microwave-assisted preparation of CdTe (core)/CdS (shell-I)/ZnS (shell-II) QDs.

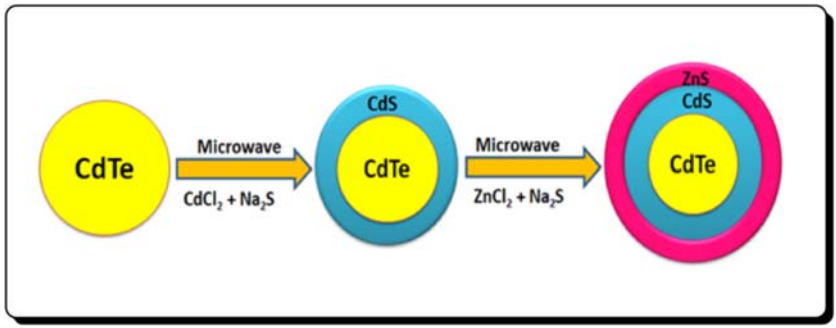

FIGURE 7.3 Microwave-assisted production of water-dispersed CdTe/CdS/ZnS core−shell−shell quantum dots. *Adapted Wang et al., 2013. Biomaterials 34 (37), 9509−9518. With Permission.*

7.4 Synthesis of alloyed quantum dots

These include multiple materials, but in the same combination. Therefore, combinations of two diverse semiconductors with unlike bandgaps may introduce some unique properties to the dots.

ZnSe QDs are interesting as these have the potential to be used in solar cells, diodes, scintillators, etc. (Abd Elhamid et al., 2018). Huang and Han (2010) have developed a simple plan for preparing GSH-capped ZnSe QDs

under MW irradiation. The Na_2SeO_3 was used as a source of Se. The GSH, zinc nitrate, Na_2SeO_3, and surplus $NaBH_4$ were mixed and exposed to MWs treatment (300 W) for 1 h. It was revealed that as-prepared ZnSe QDs had cubic shapes and ZnS spherical shapes with diameters in the range of 2−3 nm.

Qian et al. (2005) developed a seed-mediated technique for the synthesis of alloyed QDs (CdSe−CdS) under MW irradiation in aqueous phase. They prepared CdSe seeds by a reaction between Cd^{2+} and NaHSe. The MPA was used as a source of sulfide ions followed by MW exposure (1000 W). It was observed that the black-colored solution turned to white after 3 h. The NaHSe was prepared by $NaBH_4$ and Se powder. Again, the resultant solution was irradiated with MWs at for 5 min^{-1} h. It was reported that the size of alloyed QDs was 28 nm with QY of 25%.

Yang et al. (2013) synthesized CdSe-TeS alloyed QDs in aqueous solution using MW radiation. They used $CdCl_2$, NaHTe, and NaHSe as sources of Cd, Te, and Se, respectively. The MPA served as a source of sulfur and acted as a stabilizer also. These alloyed QDs could achieve 57.7% QY and are used in cancer imaging.

A simple MW treatment procedure for the preparation of $CdSe_xTe_{1-x}$−CdS QDs was reported by Luo et al. (2014). They carried out this MW-assisted method in two steps:

1. CdS shell ($CdSe_xTe_{1-x}$-CdS-I) was prepared by 3-mercaptopropionic acid capped $CdSe_xTe_{1-x}$ QDs.
2. CdS layer formation on the $CdSe_xTe_{1-x}$ core.

It was revealed that the XRD data supported the formation of alloyed QDs and the size of QDs was found to be 3.2 nm. These QDs were used in QSSCs.

Al-Hazmi et al. (2020) prepared nanocrystalline $Zn_{1-x}Pa_xTe$ ($0 \leq x \leq 0.09$) QDs using poly[(9,9-bis(3′-(N,Ndimethylamino)propyl)-2,7-fluorene)-alt-2,7-(9,9-dioctylfluorene)] via a MW-assisted method. They used a solution of poly[(9,9-bis(3′-(N,N-dimethylamino)propyl)-2,7-fluorene)-alt-2,7-(9,9-dioctylfluorene)], OLA, and 1-ODE, zinc acetate, trioctylphosphine telluride, and a sufficient amount of protactinium chloride. The resultant solution was irradiated with MWs (1200 W) for 2 h. They could obtain crystalline and monodispersed $Zn_{1-x}Pa_xTe$ QDs with a size ranging between 3 and 8 nm and very good QY up to 95%.

Mubiayi et al. (2020) synthesized $CuInGaSe_2$ QDs using MW exposure. Equal quantities and concentration of tri-n-octylphosphine (TOP) capped copper, gallium, and indium chloride in solvent OLA were mixed and MW (500 W) exposure was given for 10 min. Then TOPSe was injected and it was irradiated again with MW (600 W) for 10 min. It was observed that as-obtained QDs were pyramidal in shape with a crystalline nature and had

an average diameter of 10 nm. It was reported that films of as-prepared QDs can be applied as a counter electrode in DSSCs.

7.5 Carbon and graphene quantum dots

Graphite and GO are normally used for the preparation of GQDs. Several workers have used these precursors with different methods, but the MW technique was found to be better for this purpose. Li et al. (2012) synthesized greenish-yellow and blue GQDs (g-GQDs and b-GQDs). They did not utilize a stabilizer in this method. It was reported that PL QY of b-GQDs and gGQDs was found to be 22.9% and 11.7%, respectively. Their average diameter of QDs was found to be in the range of 2−7 nm.

The GQDs were also synthesized by Chen et al. (2012) using a MW-hydrothermal method. They used GO as the precursor of GQDs in the presence of nitric and sulfuric acids and exposed them to MWs (200°C) for 5 min. The size of as-prepared QDs was in the range of 2−5 nm. The MW-assisted hydrothermal method was also used by Chen et al. (2013) for the synthesis of pyrrole-ring functionalized GQDs (p-GQDs). They used the similar MW conditions here. It was reported that the final solution was pink and particle size ranged between 2 and 6 nm.

Shin et al. (2014) prepared GQDs directly from graphite powder in large amounts under MW irradiation (600 W) for 1 h. An average particle size of GQDs was found to be below 8 nm only. Carbon black, lamp black, and candle soot were used by Wang et al. (2011b) for the generation of CQDs.

Alves et al. (2018) synthesized grapheme TiO_2-QDs via nanoemulsification. They used different precursors of carbon (GO, Triton-X, n-heptane, OLA, OA) and titanium propoxide as precursors of TiO_2. The MW exposure (300 W) was given to get QDs of globular shape with 3.3 nm.

Li et al. (2018) prepared S, N-carbon QDs under MW irradiation for 7 min. They used thiourea as the source of dopant (S, N). Later, they used as-prepared QDs for the reduction of carbon dioxide. Jusuf et al. (2018) made use of eggshell for preparing CQDs under MW irradiation (560 W) for 2 min CQDs and used these QDs in the degradation of pollutants. It was reported that as-prepared CQDs were 3.88 nm in diameter. Yang et al. (2018) used xylan and ammonium hydroxide as a carbon-precursor and source of dopant (N) to prepare fabricate nitrogen-doped CQDs under an MW approach (200 W) for 10 min. A change in color of the solution was observed from dull yellow to brown.

7.6 Recent developments

There has been rapid progress in the field of MW-assisted synthesis of different QDs and their varied applications in last few decades. Some recent advances are summarized in Table 7.1.

TABLE 7.1 Synthesis of quantum dots under microwave irradiation.

Quantum dots	Size (nm)	Applications	References
CdTe	2.6–3.5	Ratiometric fluorescence sensor	Amiri and Hosseini (2020)
$CuInGaSe_2$	10	Ultrasonic spray system	Mubiayi et al. (2020)

7.7 Conclusion

This chapter highlights the generation of QDs by MW-assisted synthesis. These QDs have found various applications in varied fields such as sensors, LED, photocatalyst, solar cells, biomedicals (drug target delivery, cancer therapy, biolabeling, bioimaging, etc.). One can control/modify the parameter of QDs. This technique has many other advantages over conventional methods. The MW process has also been used in combination with solvothermal, ultrasound, and hydrothermal methods for a better yield and within a limited time, that is, within minutes or sometimes even in seconds. The use of MW technique has great potential in providing uniform and homogeneous QDs and it will prove to be an asset in the years to come.

Chapter 8

Sonochemical synthesis of quantum dots

Garima Ameta[1] **and Seema Kothari**[2]
[1]*Department of Chemistry, M. L. S. University, Udaipur, Rajasthan, India,* [2]*Department of Chemistry, PAHER University, Udaipur, Rajasthan, India*

8.1 Introduction

Sound frequencies beyond the upper audible limit of human hearing are normally categorized as ultrasound. The frequency range of ultrasound that has been used sonochemistry is 16−3000 kHz. Ultrasonic irradiation has been widely used in chemical synthesis and it has become an interesting field of research. When an ultrasonic wave passes through a liquid medium, than a large number of microbubbles are formed, they grow, and finally collapse in a very short time, which is of the order of a few microseconds. This is called ultrasonic cavitation (Fig. 8.1).

Extremely high pressures and temperatures are generated during the process of acoustic cavitation, which initiates a number of chemical and physical effects, such as microjetting, shock waves, shear forces, microstreaming, and generation of different radicals. Sonochemistry finds a variety of applications such as drug encapsulation and delivery, food science, electrochemistry, material engineering, synthesis of nanoparticles, etc.

Bang and Suslick (2010) have reviewed the application of ultrasound in the synthesis of nanostructured materials. Sonochemical approach can provide control morphology over size. Cavitation-induced sonochemistry with the temperature and pressures provides hot spots inside the bubbles of the order of ∼5000 K, and ∼1000 bar, respectively. These extraordinary conditions permit the synthesis of a wide range of nanostructured materials, particularly quantum dots.

The field of sonochemistry has been excellently delivered by various workers over time (Einhorn et al., 1989; Pestman et al., 1994; Mason, 1999; Suslick and Flannigan, 2008; Ameta et al., 2018).

The high energy and pressure for chemical reaction is generated by collapsing bubbles. This can be divided into three regions (Fig. 8.2):

Quantum Dots. DOI: https://doi.org/10.1016/B978-0-12-824153-0.00008-2

Sonochemical degradation of chlorinated organic compounds, phenolic compounds and organic dyes—a review. Sci. Total. Environ., 2009, 407 (8), 2474—2492. With permission.*

1. First region is a hot spot region or thermolytic center, which has a quite high temperature of 5000 K and a high pressure of 500 atm during the collapse of a bubble or cavitation.
2. Second region is a interfacial region between the bulk liquid cavitation bubble.
3. Third region is a bulk region. Here, temperature is almost equal to room temperature due to process of adiabatic cavitation.

8.1.1 Advantages

There are some advantages of using the sonochemical route for the synthesis of quantum dots. These include:

1. It improves the reaction rate.
2. It involves high energies and pressures in a short time.
3. No additives are required.
4. It reduces the number of reaction steps.
5. It provides uniform size distribution, higher surface area, with improved phase purity.
6. It is a solvent-free synthesis producing less waste.

8.1.2 Disadvantage

The sonochemical method has a disadvantage as:

1. It affords relatively low yield of the product.

8.2 Instrumentation

Various sources are used for generating ultrasound.

1. The first ultrasound transducer was developed by Galton (1883), now known as Galton's whistle (Fig. 8.3A). It is a brass tube and a jet of gas is passed through an orifice into a resonating cavity.
2. Liquid whistle is also used for this purpose (Fig. 8.3B). Cavitation is generated in this transducer through motion of a liquid in place of gas.
3. Piezoelectric transducers are also used for generation of ultrasound (Fig. 8.3C). A transducer is based on electrical and mechanical vibrations via piezoelectric effect. There are many materials that have a range of piezoelectric effects. Some examples of natural materials are quartz, topaz. tourmaline, belemnite, etc., while synthetic materials are bismuth ferrite, lithium tantalite, $Ba_2Na\ Nb_5\ O_5$, $Pb_2KNb_5O_{15}$, etc.
4. Cup horn (Fig. 8.3D). It is a high intensity ultrasonic bath. In this transducer, indirect sonication technology is involved. This cup horn sonication is effective, where the liquid sample is higher in volume.

8.3 Synthesis of quantum dots

8.3.1 Metals

Liu et al. (2011) prepared highly fluorescent and water-soluble gold nanoclusters (AuNCs) and Au@AgNCs emitting near-infrared via a sonochemical approach. It was reported that yellow emission was observed from Au@AgNCs. It was revealed that as-prepared Au NCs could be successfully applied in the determination of copper ions in a wider of range of concentration with a lower of limit NCs. A facile and fast sonochemical route was proposed by Wang et al. (2017) to synthesize fluorescent AgNCs. They used glutathione (GSH) and hydrazine hydrate, respectively, as capping and reducing agent. It was revealed that

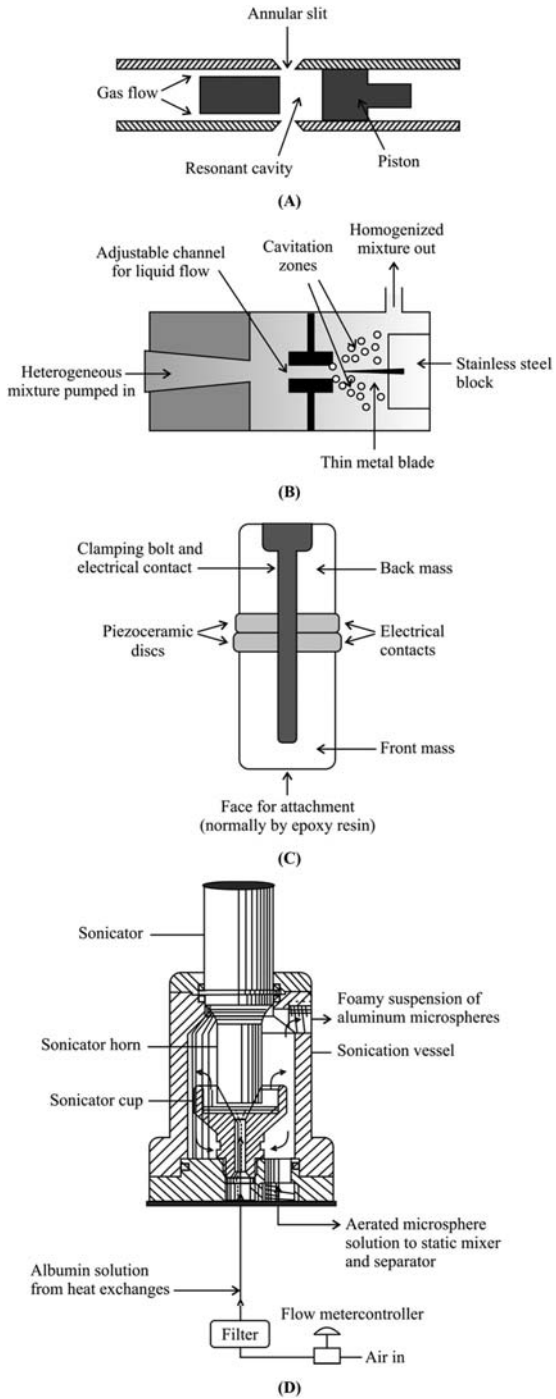

FIGURE 8.3 Various sources for ultrasound generation: (A) Galton whistle; (B) liquid whistle; (C) piezoelectric transducer; and (D) cup horn. *Adapted from Ameta et al., Sonochemistry: An Emerging Green Technology, Apple Academic Press, New Jersey, 2018, With Permission.*

AgNCs waweres formed quickly within 15 min in the presence of ultrasonic waves. As-prepared QDs show red fluorescence and good dispersion in aqueous solution. The size of AgNCs was found to be small enough ($\sim$2 nm). Use of GSH as protecting agent on the surface of these AgNCs provides high, photo-, and pH-stability. They designed a stable Ag nanoclusters-based nanosensor for detection of Pb^{2+} ions with high sensitivity and selectivity. The as-fabricated nanosensor can also be used as a probe for monitoring Pb^{2+} ions in living cells. It was proposed that these stable and fluorescent AgNCs can find potential applications for sensing and biolabeling.

Mallikarjuna et al. (2021) fabricated g-C_3N_4 and Ag-g-C_3N_4 composite structures by the ultrasonication method. It was reported that the silver quantum dots anchored to g-C_3N_4 structures may show better photocatalytic activities for dye degradation, H_2 production, and antimicrobial activity in the presence of visible-light. As-prepared Ag/g-C_3N_4 composite (Ag loading of 0.02 mole) exhibited optimum photoactivity for production of H_2 (335.40 $\mu molg^{-1}h^{-1}$), which is much better than other Ag loaded g-C_3N_4 composites. These synthesized Ag/g-C_3N_4 nanoparticles also show potential antimicrobial activity and inhibition zones were found comparable to that of an antibiotic chloramphenicol. Calderón-Jiménez et al. (2022) reported a sonochemical synthesis of silver nanoparticles in aqueous suspension. These Ag NPs were found to be quasi-spherical in shape and highly stable. The particle size of as-prepared sample was found to be 8.1 $\pm$ 2.4 nm with narrow dispersion of the size distribution. The bandgap of these Ag NPs was 2.795 $\pm$ 0.002 eV. A high stability of the optical properties of these Ag NPs were found at 10 h (short term) and 24 weeks.

8.3.2 Metal oxides

Sedghi et al. (2010) prepared SnO_2 QDs by sonication-assisted precipitation. It was reported that they can be used as a low temperature sensor for detecting CO as well as methane. There was a good of selectivity to CO in the presence of methane below 375°C using this sensor. The average particle size of SnO_2 QDs was found to be 3−4 nm and their sensing properties were compared with the nanoparticles prepared by conventional sol−gel method. It was observed that bandgap measurements of as-prepared sample indicated a 2.1 eV blueshift. Majumdar and Devi (2010) synthesized SnO_2 nanoparticles at room temperature by a sonication-assisted precipitation method. It was reported that 3 h sonication was found to produce nanoparticles with size below 10 nm. It was found that a gradual increase of the sonication time gradually decreases the particle size with interesting morphology and increased surface area. It was also observed that as-synthesized powders exhibited a direct influence by the sonication time on the sensing properties of butane. A maximum response of 98.88% was reported toward butane (5000 ppm) at 450°C along with a fast recovery time.

A sonochemical approach was developed by Islam et al. (2011) for large-scale synthesis of iron oxide magnetic nanoparticles (Fe_3O_4 NPs) using inexpensive and nontoxic metal salts as reactants. It was revealed that as-prepared nanoparticles had average particle size around 11 nm and these were almost spherical in shape. It was also proved that these particles were super paramagnetic with magnetization values of 80 emu g^{-1}. Chlorine-doped titanium dioxide (anatase) nanocrystallites were prepared by Wang et al. (2012) through sonicating sodium chloride solution of tetraisopropyl titanate in water/ethanol at 70°C. The presence of dopant (chloride) was confirmed and it was found that Cl is incorporated into TiO_2. It was reported that as-prepared samples were used in the photodegradation of butyl benzyl phthalate (BBP) in aqueous condition in the presence of visible light irradiation. It was reported that photodegradation of BBP could reach to 92% in 4 h.

N-doped TiO_2 nanocrystals were synthesized by Jia et al. (2014) via a sonochemical route. The urea, titanium tetrachloride, and aqueous ammonia were used as starting materials. It was revealed that as-synthesized nanocrystals had size of 10 nm. It was reported that the adsorption band edge of N-doped TiO_2 samples exhibited redshift to the visible region compared to TiO_2. The photocatalytic activity of as-prepared photocatalyst was observed for degradation of rhodamine B under visible light. It was revealed that the use of an optimal amount of urea enhanced the photocatalytic activity of TiO_2 due to its mesoporous structure and incorporation of nitrogen as a dopant.

Yang et al. (2016a) synthesized ZnO quantum dots using an ultrasonic microreactor. It was observed that flow rate, ultrasonic power, and temperature affected type and quantity of defects in ZnO quantum dots, and size of ZnO quantum dots can also be controlled by variation of these conditions. It was reported that the size of ZnO quantum dots decreased on increasing flow rate but quantum yields first increased and then decreased. The size of ZnO quantum dots was found to decrease first, and then increased on increasing ultrasonic power while the quantum yields kept on increasing. Moreover, the quantum yields of ZnO QDs synthesized by ultrasonic microreactor could reach 64.7%, which is higher than those synthesized only under ultrasonic radiation or only by microreactor.

The ZnO quantum dots were synthesized by Yang et al. (2016b) using an ultrasonic-assisted sol−gel method. It was reported that ultrasonic exposure time and temperature both affected type and amount of defects in as-prepared ZnO quantum dots. Total defects of ZnO quantum dots were found to decrease with the increasing ultrasonic time and temperature. The optical defects changed from oxygen interstitial defects to oxygen vacancy and then zinc interstitial defects. These were again transformed back to oxygen interstitial defects. It was observed that the sizes of ZnO quantum dots first decreased on increasing ultrasonic temperature and time and then increased.

Moghaddam et al. (2017) prepared two samples of ZnO quantum dots by sonochemical as well as conventional methods. It was indicated that the quantum dots prepared under ultrasonic waves had smaller size and also a narrow size distribution. It was observed that phase purity of nanocrystals could be obtained on using ultrasonic waves as there is complete conversion of precursors into ZnO, and as a result as-prepared ZnO can find application in optoelectronics.

8.3.3 Metal sulfides

The histidine functionalized CdS quantum dots were synthesized by Yadav et al. (2010) via a sonochemical method. It was revealed that as-prepared CdS QDs are well-defined with almost spherical shape. The X-ray diffraction pattern indicates the formation of cubic phase QDs. The confinement of histidine functionalized CdS QDs was confirmed. The photoluminescence property of CdS/histidine QDs was found to be better than that of CdS QDs. These as-functionalized QDs can find potential applications in the biological fields. Estandarte et al. (2011) synthesized ionic liquid-capped cadmium sulfide QDs in PET fibers as photocatatyst. Its photocatalytic activity was evaluated in the photodegradation of methylene blue. These CdS QDs and PET-CdS QDs nanocomposites were synthesized via a sonochemical route using an ionic liquid, 1-octyi-3-methylimidazolium lauryl sulfate ([OMIM]LS). They used PET fibers prepared from waste bottles and used these as matrix for preparation of the PET-CdS QDs nanocomposite. It was revealed that PET-CdS QDs nanocomposite has the highest bandgap energy (2.79 eV), which is suitable for absorption in the visible range. The CdS QDs and PET-CdS QDs nanocomposites were used as photocatalyst for photodegradation of methylene blue under visible light and degradation efficiency was 53.64 and 77.96%, respectively, which was much better than uncatalyzed degradation (19.57%).

Semiconductor nanoparticles of CdS have been prepared by Entezari and Ghows (2011) in microemulsion (O/W) under ultrasound irradiation. The effect of some operational parameters was observed, such as intensity of ultrasound, sonication time, temperature, and oil fraction. It was observed that as-prepared QDs had about 2 nm size with a hexagonal phase and this size can also be tuned. It was postulated that the collapse of bubbles generates high temperature and a number of nucleation sites, thus leading to uniform spherical particles with small size. It was revealed that the bandgap of as-prepared CdS NPs decreases with increasing sonication time. Goharshadi et al. (2012) developed a sonochemical method to prepare zinc sulfide nanoparticles with extremely small size (about 1 nm in diameter). They used a set of ionic liquids, which are based on the bis(trifluoromethylsulfonyl)imide anion and different 1-alkyl-3-methyl-imidazolium cations. This method provides wide bandgap ZnS nanocrystals, which can find application in different photonic devices.

A template-free chemical and sonochemical method was developed by Pejova and Bineva (2013) to prepare 3D assemblies of indium(III) sulfide quantum dots. This method allowed the deposition of cubic α-In2S3 nanocrystals (close packed) in thin film because of heterogeneous sonochemical effects. The average crystal radius of QD was reduced from 2.5 to 2.0 nm on sonication by continuous high-intensity ultrasound. It was observed that these values increased to 4.1 nm by postdeposition annealing treatment. It was reported that bandgap energy value (2.85 eV) was blueshifted (2.00 eV). It was revealed that Bohr's excitonic radius lies in the range of 2.5−4.1 nm.

Zhao et al. (2013) synthesized gamma-cyclodextrin-folate (gamma-CD/FA) inclusion-coated CdSe/ZnS quantum dots by a sonochemical method. It was observed that these gamma-CD/FA-coated CdSe/ZnS QDs were monodispersed and have smaller size, but with longer fluorescence lifetime and higher quantum yield. The cytotoxicity of gamma-CD/FA-coated CdSe/ZnS QDs was found to be lower and they could more effectively enter cancer cells. It is the smaller size of QDs (4−5 nm diameters) that allowed them to easily enter the cell and be removed through kidneys. These QDs are more suitable for some biomedical applications like bioprobes and bioimaging.

Das and Wai (2014) synthesized lead sulfide quantum dots. They used 1,2-benzenedimethanethiol, sodium sulfide, and lead nitrate solutions in ethanol under ultrasound irradiation. As-prepared PbS quantum dots had sizes of 2.7 and 3.6 nm in diameter. A simple one-pot method for synthesis of SWNT−PbS nanoparticle composite was also developed just by addition of single-walled carbon nanotubes (SWCNT) to the system under ultrasonic irradiation. This allowed the attachment of PbS nanoparticles to the SWCNTs' surface via π−π stacking. Kim et al. (2015) synthesized CdS quantum dots (QDs)/mesoporous TiO_2 (mp-TiO_2) by a sonochemical successive ionic layer adsorption and reaction (SC-SILAR) process. It was found that there is less growth time and larger absorbance of CdS QDs along with a uniform penetration into mp-TiO_2 films in the case of the SC-SILAR process as compared to the SILAR process. As-prepared CdS QDs/mp-TiO_2 was used to fabricate photoanode. This was used in quantum dot-sensitized solar cells (QDSCs) and these cells exhibited high efficiency.

Palanisamy et al. (2015) developed a continuous flow sonochemical reactor, which can produce metastable cadmium sulfide nanoplatelets. It was observed that continuous sonochemical synthesis was found to give high aspect ratio for hexagonal platelets of CdS with cubic crystal structures with thicknesses below 10 nm. It was revealed that uniformity in particle size was much better, when the continuous sonochemical process was used as compared to conventional synthesis processes and batch sonochemical process.

Xu et al. (2015) synthesized uniform molybdenum disulfide/tungsten disulfide quantum dots by the combination of solvothermal and sonication treatment. They used bulk MoS_2/WS_2 reactants at a mild temperature. It was observed that monolayer thickness had an average size of 3 nm. It was

reported that a highly exfoliated and defect-rich structure provides these quantum dots with enough active sites for catalyzing the hydrogen evolution reaction (HER) with long-term durability. These as-prepared particles had good cell permeability, strong fluorescence, and low cytotoxicity, which make them quite promising and biocompatible probes for imaging.

Sonochemical method for the synthesis of zinc sulfide quantum dots has been developed by Panda et al. (2016). They used a single precursor Zn ion and sulfur containing complex. It was indicated that the prepared complexes decomposed to form zinc sulfide quantum dots under high intensity ultrasound irradiation. It was revealed that as-obtained ZnS quantum dots had an 8.2 nm diameter with a cubic structure. The bandgap of these ZnS QDs was also calculated and was found to be 3.73 eV. The Cu and Mn-doped glutathione (GSH)−ZnS polypeptide quantum dots were prepared by Shi et al. (2016) via microwave-assisted sonochemical approach. The glutathione acted as a source of sulfide as well as a dispersant and reducing agent to form polypeptide QDs. It was indicated that the size of the polypeptides QDs was 2−3 nm. It was also reported that the doping of Cu and Mn could decrease the bandgap of GSH−ZnS from 3.67 to 2.86 eV. It was observed that photoelectrochemical (PEC) properties of GSH−ZnS were also enhanced due to the doping of Mn and Cu with excellent chemical stability.

ZnS quantum dots and ZnS:graphene QDs were synthesized by Jindal and Giripunje (2016) via a sonochemical method. It was reported that the average size of ZnS and ZnS:graphene QDs was 3.7 and 8.4 nm, respectively. The bandgap of ZnS:graphene QDs was calculated as 4.9 eV. An increase in current density from 2.44 to 98.4 $\mu A\ cm^{-1}$ was observed with lower turn on voltage from 0.40 to 0.12 V in the active layer as compared to pristine ZnS QDs. Such an enhancement in current density in these ZnS:graphene QDs indicated a great potential for such an active layer in photovoltaic devices. Kapatel et al. (2017) reported the synthesis of tungsten disulfide quantum dots, which were highly stable. They used sodium chloride, sodium hydroxide, lithium hydroxide, and ammonium hydroxide-assisted sonochemical exfoliation of bulk WS_2 powder in N-methyl-2-pyrrolidone for 2 h. It was observed that as-prepared WS_2 quantum dots (few-to-monolayer) have a size of 3 ± 0.5 nm. It was also revealed that better yield of WS_2 quantum dots was obtained in N-methyl-2-pyrrolidone. The as-obtained WS_2 quantum dots exhibited a blueshift with a bandgap of 2.7 eV.

Tin sulfide quantum dots were synthesized by Cheraghizade et al. (2017) via a sonochemical method. They kept sonication time as 10, 15, and 20 min. It was reported that SnS and Sn_2S_3 (orthorhombic phase) and Sn_2S_3 (hexagonal phase) was there in as-prepared QDs. The particle size of tin sulfide QDs was smaller than other QDs, when sonication time was kept at 20 min. It was revealed that smaller spherical shaped particles were obtained on increasing sonication time. The solar cell devices manufactured using tin sulfide QDs exhibited a better performance with the samples prepared with

more sonication time. It was concluded that sonication time is the key factor affecting the synthesis of Sn_2S_3 QDs. Not only this, it will also affect photocatalytic, optical, electrical, and photovoltaic conversion.

Kadeer et al. (2018) synthesized CdS quantum dots/Bi_2WO_6 three-dimensional (3D) heterojunction photocatalyst by ultrasonic method. These composites were found to be active for the degradation of rhodamine B and tetracycline hydrochloride under visible light irradiation and also for the reduction of Cr(VI) in aqueous solution. As-prepared CdS QDs/Bi_2WO_6 heterojunctions exhibited a significantly enhanced photocatalytic activity in all these cases as-compared with samples of CdS and Bi_2WO_6. The highest photocatalytic efficiency for degradation of rhodamine B was 94.5% with 3% CdS QDs/Bi_2WO_6 heterojunction in 30 min, which was about 6 and 1.5 times higher than that with those of pure Bi_2WO_6 and CdS QDs respectively. This enhancement was attributed to the synergetic effect between CdS QDs and Bi_2WO_6, including fast transfer of charge carriers between CdS QDs and Bi_2WO_6 and an efficient electron−hole separation.

Rajabi et al. (2018) developed a sono-assisted chemical precipitation method for synthesizing zinc sulfide quantum dots at room temperature. Then ZnS QDs doped with some transition metal ions (Ag, Mn and Cu) were also prepared using l-cysteine as the capping agent. It was revealed that the time required for a complete synthesis in the presence of ultrasonic irradiations was less than other conventional chemical methods. It takes hardly 15 min at a temperature of 40°C. The bandgap of colloidal ZnS QDs was found to be larger than 3.68 eV. The average particle size of these QDs was less than 5 nm. These were then used for driving the photocatalytic process for degradation of Victoria blue R. It was reported that the maximum removal of this dye (>95%) could be achieved under optimum conditions: pH 10.5, amount of QDs 3 mg, and time 30 min under UV irradiation. It was also revealed that these QDs can be reused six further times, without any significant loss in their photocatalytic properties.

A chemical precipitation method was used by Karimi et al. (2019) for thesynthesis of zinc sulfide quantum dots under the ultrasonic radiation, which was water based and fast also. They used two capping agents, l-cysteine and 2-mercaptoethanol, for this purpose. It was indicated that as-synthesized QDs were cubic in structure with a size less than 10 nm. These ZnS QDs were then used as photocatalysts for the degradation of crystalline violet under UV light. It was revealed that as-synthesized QDs can be reused five times without any significant decrease in their photocatalytic activities.

The cadmium sulfide QDs-sensitized mesoporous-TiO_2 (mp-TiO_2) photoanodes were fabricated by Kim et al. (2019) using the sonochemical successive ionic layer adsorption and reaction (SC-SILAR) methods to achieve highly efficient quantum dots (QDs)-sensitized solar cells. It was reported that the SC-SILAR method took a shorter time for synthesis of CdS QDs as

compared to the conventional SILAR method. It was suggested that the cavitation energy of microbubbles formed in the SC-SILAR method provided an additional energy for the synthesis of CdS QDs. Kandasamy et al. (2022) synthesized cadmium sulfide quantum dots through a green sonochemical method. They used *Delonix elata* leaves water extract as a capping as well as stabilizing agent. It was reported that the corrosion inhibition performance of as-prepared CdS QDs was studied in 3.5% NaCl, 1 M HCl, and 6 M KOH. It was observed that corrosion of zinc plate was reduced when the plates were coated with CdS QDs and these aqueous electrolytes, particularly with 3.5% NaCl.

Goharshadi et al. (2013) synthesized zinc sulfide nanoparticles under ultrasonic irradiation. They did not use any surfactant in this method under high temperature treatment. It was reported that the average particle size of as-prepared ZnS QDs was found to be 2 nm. The photocatalytic activity of ZnS quantum dots was evaluated for the degradation of reactive black 5 under UV light irradiation. It was revealed that about 95% of dye was removed within 10 min when using 0.2 g ZnS at a neutral pH.

8.3.4 Selenides

Three-dimensional (3D) assemblies of CdSe quantum dots (zinc blende structure) were synthesized by Pejova (2013) by two routes: (1) colloidal chemical and (2) sonochemical. A decreasing trend was observed on postdeposition thermal annealing treatment, with increasing average crystal size. Mousavi-Kamazani et al. (2016) synthesized $NiSe_2$ quantum dots from the reaction of selenium tetrachloride with pomegranate marc peels (PMP) dyes and Ni as a nickel precursor in the presence of potassium borohydride through a sonochemical-assisted method. They used PMP because it has several dyes (proanthocyanidins) and flavonoids and ions that can easily extract these from PMP.

Tavakolian and Tashkhourian (2018) prepared cadmium selenide quantum dots capped with reduced graphene oxide and then modified with thioglycolic acid in only 5 min under sonication. They used a solution of cadmium(II) nitrate, graphene oxide, thioglycolic acid, and selenium powder with $NaBH_4$ for this purpose. The glassy carbon electrode (GCE) was modified with as-prepared nanocomposite and used for the determination of ascorbic acid (AA), dopamine (DA), and uric acid (UA) simultaneously. The detection limit was found to be 0.11, 66 and 0.12 μM for DA, AA and UA, respectively. This electrode was also successfully applied for determination of these compounds in spiked urine samples. Kastilani et al. (2019) reported the sonochemical synthesis of CdSe quantum dots in single-liquid bulk phase as well as emulsion-based system. They used cadmium oleate and trioctylphosphine selenide as precursors. It was observed that synthesis of QDs was found to be slow in the case of a single-phase liquid system (1-octadecene)

but it was quite enhanced in a dispersed system (emulsions of 1-octadecene in ethylene glycol). It was also observed that the single-phase solvent system produced ultrasmall QDs exhibiting white-light emission (broad band), while the emulsion system produced well-defined magic-size clusters (MSCs) with high photoluminescence quantum yield (34%).

An ultrasound-assisted method was used by Zare and Tashkhourian (2020) for synthesis of L- and D-cysteine-capped CdSe quantum dots at room temperature. It was observed that as-prepared QDs were in the range of 5−7 nm diameters. These capped QDs exhibited green fluorescence, which was quenched differently by D- and L-tryptophen in a high selective manner, so that they can be used for their recognition with negligible interference by other species. It was reported that detection limits for the recognition of L- and D-tryptophen are 4.2 and 4.7 nm, respectively. However, it was 4.4 and 4.8 nm in the presence of other enantiomers. Tb-doped CdSe nanoparticles were synthesized by Hanifehpour et al. (2021) with variable Tb^{3+} content via a sonochemical route. The sonophotocatalytic activities of the as-prepared sample were evaluated for the photodegradation of reactive black 5. It was reported that the sonophotocatalytic process could degrade 85.25% of the dye, which was much more compared to individual sono- (22%) and photocatalytic degradation (8%) processes. It was observed that photodegradation was inhibited in the presence of benzoquinone and ammonium oxalate. Superoxide radicals and photogenerated holes were detected as the main oxidative species.

8.3.5 Tellurides

Luminescent CdTe quantum dots were produced in an aqueous medium by Menezes et al. (2011) within a few minutes using ultrasound irradiation. It was reported that as-produced QDs exhibited a strong quantum confinement effect and only one fluorescence band was present. These nanoparticles were monodispersed. It was revealed that the morphology of QDs can be better controlled and surface defects are also reduced by the use of ultrasound. The colloidal cadmium telluride quantum dots have been synthesized by Hwang et al. (2011) via one-pot sonochemical reaction. They used multibubble sonoluminescence (MBSL) conditions for this work. The tellurium powder and cadmium chloride with hexadecylamine and trioctylphosphine/trioctylphosphineoxide (TOP/TOPO) (dispersants) were sonicated in toluene (solvent) using ultrasound (20 kHz) at 60°C for 5−40 min. It was reported that a very wide size range of CdTe particles (2−30 μm), could be obtained by just controlling sonicating and thermal heating conditions. It was observed that as-prepared CdTe QDs exhibited different colors, ranging from pale yellow to dark brown, and they showed photoluminescence properties mainly due to the quantum confinement effect. The bandgap of these CdTe particles was found to be 1.53 eV.

Chen et al. (2012) prepared highly fluorescent and water-soluble CdTe quantum dots. They used β-cyclodextrin (β-CD) as surface-coating agents. This

involved a substitution reaction at the C-6 position of mono-6-deoxy-6-(p-tolylsulfonyl)-cyclodextrin (6-tso-β-CD) by the $-NH_2$ of (3-aminopropyl)triethoxysilane-coated CdTe QDs to afford APTES/ CdTe QDs under mild conditions. It was proved that the CdTe QDs were effectively modified by β-CD. The quantum yields of CdTe QDs, APTES/CdTe QDs, and β-CD/APTES/CdTe QDs in water were about 17%, 12%, and 9%, respectively. It was reported that β-CD/APTES/CdTe QDs could recognize molecules of p,p′-DDT and o,p′-DDT.

Shi et al. (2014) developed a fast one-pot method for synthesis of CdTe quantum dots in aqueous solution using a sonoelectrochemical route without the protection of N. It was indicated that the water-soluble CdTe QDs with high photoluminescence qualities can be synthesized without the preparation of precursor and N protection. The PL emission wavelength and quantum yield can be controlled by variation of some operational parameters. It was suggested that QDs prepared by this method have a great potential for application in the fields of sensors, photocatalysis, and solar cells. The cadmium telluride quantum dots were synthesized by Yoo et al. (2017) under ultrasonic irradiation. It was observed that bandgap reduces with the growth of CdTe quantum dots on increasing time of synthesis. There was a redshift in wavelength range (510 ~ 610 nm) on increasing the ratio of Te and cubic zinc blende structure was observed. The size of CdTe quantum dots was found to be about 2.5 nm and these were uniformly dispersed, when the time of synthesis was 210 min.

8.3.6 Carbon-based quantum dots

Li et al. (2011) synthesized monodispersed water-soluble fluorescent carbon nanoparticles. They used glucose as the source of carbon by a one-step alkali or acid-assisted ultrasonic treatment. It was reported that particle surfaces were quite rich in hydroxyl groups so as to provide a high hydrophilic nature. These could emit bright and colorful photoluminescence covering a broad range starting from visible to near infrared (NIR). It was also revealed that these particles had an excellent upconversion fluorescent properties also.

Bavireddi and Kikkeri (2012) synthesized highly fluorescent water-soluble glycoquantum dots through a sonochemical method. It was based on specific host−guest interactions between trioctylphosphine oxide (TOPO) surfactant and β-cyclodextrin (β-CD) on quantum dots. It was indicated that these QDs (β-CD modified) provided good cell viability of human hepatocellular carcinoma cell line (HepG2) cells. It was also revealed that β-CDgal-capped QDs can have a preferential binding with HepG2 cells and therefore could be a promising candidate for some biomedical applications.

Composite architectures consisting of graphitic carbon nitride quantum dots/bismuth phosphate were synthesized by Li et al. (2014). Then as-synthesized composite was used as a visible light-induced photocatalyst for photodegradation of methyl orange with appreciable efficiency.

A one-step sonochemical preparation of carbon dots (C-dots) doped with Ga atom (Ga@C-dots) have been reported by Kumar et al. (2015). This synthesis was carried out with molten Ga, and polyethylene glycol (PEG-400) as the reaction medium for 30−120 min under sonication. It was revealed that as-produced Ga@C-dots in PEG supernatant had an average diameter of 5 ± 2 nm. The fluorescence emission of Ga@C-dots was used as a probe and compared with pristine C-dots.

Kumar et al. (2016a,b) also used a sonochemical approach for the formation of C-dots using ultrasonic irradiation. They sonicated a two-phase mixture to yield Sn@C-dots and achieved Sn nanoparticles decorated by Sn@C-dots (Sn@C-dots@Sn). They directly deposited as-synthesized Sn@C-dots@Sn nanoparticles on the copper foil (current collector) and used them as a promising anode for Li-ion batteries. It was revealed that high lithiation and delithiation properties were present in Sn@C-dots@Sn nanoparticles with enhanced rate capabilities and high coulombic efficiency due to the conducting carbon dot network on the tin nanoparticles minimizing pulverization effects. They also reported a one-step synthesis of carbon dots (Kumar et al., 2016a,b) via sonication of polyethylene glycol (PEG-400) for 0.5−3 h. They also observed the effect of the different operational parameters on the size and the fluorescence of the C-dots such as temperature, amplitude, and sonication. The average diameter of the C-dots was found to be in between 2 and 9 nm; of course, it depends on the conditions of preparation. The highest quantum yield of emissions was found to be $\sim$16%. High fluorescence properties of C-dots can find applications in bioimaging and solar cells.

Sajjadi et al. (2017) prepared cadmium selenide/graphene quantum dots (CdSe/g-QDs) nanocatalyst via a three-step sonochemical−hydrothermal process. It was observed that they have a small bandgap and large specific surface area. It was also observed that the sonocatalytic activity of as-synthesized CdSe/g-QDs was enhanced in the degradation of methylene blue as compared to pure CdSe nanoparticles. It was reported that the degradation efficiency of methylene blue could reach 99% in 90 min under ultrasonic irradiation in the presence of CdSe/g QDs. It was revealed that degradation efficiency increased on the addition of $K_2S_2O_8$ and H_2O_2 as enhancers, while the presence of carbonate, sulfate, and chloride had an adverse effect. It was also indicated that the CdSe/g-QDs sonocatalyst can be reused for up to five successive runs.

The graphene/Ag_3PO_4 quantum dot (rGO/Ag_3PO_4 QD) composite was synthesized by Reheman et al. (2018) via photoultrasonic-assisted reduction method. It was confirmed that as-obtained Ag_3PO_4 QDs were of the size of 1−4 nm and these were dispersed uniformly on rGO nanosheets. The photocatalytic activity of as-synthesized rGO/Ag_3PO_4 QD composites was evaluated for the decomposition of methylene blue. It was found that the best results were obtained when the ratio W_{rGO}:$W_{composite}$ was kept at 2.3%. This composite could degrade 97.5% of methylene blue within 5 min. It was

indicated that enhanced photocatalytic activities and stabilities were due to a synergistic effect between rGO and Ag_3PO_4 QDs with a high specific surface area. It was suggested that these rGO/Ag_3PO_4 QDs photocatalysts can find a great potential in water splitting and sewage treatment. Kumar et al. (2019) used sonochemistry to develop a one-pot synthesis of carbon dots, and metal-doped CDs M@CDs (where M = Zn, Ag, Ga, and Au). The size of these CDs was found to range between 2 and 10 nm. The highest quantum yield of fluorescence emission was measured as ~16%. It was revealed that M@CDs can be used for imaging and neuronal interactions. They also have potential selective affinity, photostability, and biocompatibility. As-prepared M@CD nanocomposites were biocompatible, as well as photostable, so that these can be used for different multifunctional biomedical applications.

Lu and Zhou (2019) prepared fluorescent carbon quantum dots via a sonochemical approach. As-prepared QDs were low cost with high efficiency. They prepared nitrogen-doped CQDs (NCQDs) by ultrasonic treatment of dopamine in dimethylformamide for 8 h. It was reported that as-obtained NCQDs had high water dispersibility as well as stability, within a range of pH and ionic strength, and exhibited bright and stable fluorescence, high photostability, and low cytotoxicity. The fluorescence of CQDs can be quenched by Fe ions in the range of 0−50 μm in both water as well as in the interior of cancer cells. The limit of detection was found to be 38 nm. It was also proposed that the QDs can serve as a nanothermometer to sense temperature both in water as well as in cells.

A template-free sonochemical synthesis of α-Bi_2O_3/C-dots was reported by Sharma et al. (2019). It was confirmed that α-Bi_2O_3 in the nanocomposite was present in monoclinic phase and crystallite size with 28.75 nm. The bandgap of as-prepared nanocomposite was determined to be 2.49 eV. This photocatalyst was used for photocatalytic degradation of 86% of indigo carmine dye under visible light. It was reported that dye was degraded in 2 h as compared to pure α-Bi_2O_3, which only degraded 57%. The Bi_2O_3/C-dots could also achieve about 79% degradation of levofloxacin within 2 h. It was revealed that hydroxyl radicals and electrons played major roles in the photocatalytic degradation of indigo carmine, as evident from scavenger studies.

Yuan et al. (2019) reported a sonochemistry-assisted synthesis of hybrid black/red phosphorus quantum dots (BP/RPQDs). As-prepared quantum dots have small sizes, tunable bandgaps, and high absorption coefficients. They can find application in dye-sensitized solar cells (DSSCs). It was observed that as-prepared hybrid BP/RPQDs exhibited high light-response over a wide range of wavelength (ultra-violet to visible and even near-infrared region) along with longer recombination lifetime of photo generated carriers. It was revealed that DSSCs with BP/RPQDs and BP/RPQDs-N719 cosensitizer could achieve efficiencies of 0.12% and 8.02%, respectively as compared to 7.60% for N719-only solar cell.

Kaimal et al. (2022a) synthesized graphene quantum dots (GQDs) via ultrasonication and fabricated a glassy carbon electrode embedded on

amine-functionalized silica nanoparticles (Si NPs). It was reported that as-developed electrode exhibited a good response to glutathione (most abundant antioxidant in the majority of cells and tissues) with a wide linear range (0.5−7 μm) and a low detection limit of 0.5 μm with high sensitivity. It was revealed that reproducibility, outstanding selectivity, and long-term stability of these as-prepared QDs can find application in real sample analysis even in the presence of interferences.

Kaimal et al. (2022b) prepared gold-loaded boron-doped graphene quantum dots (Au@B-GQDs) interface using the ultrasound-aided reduction method. A sensor was constructed by depositing these as-prepared Au@B-GQDs (thin layer) on a glassy carbon (GC) electrode and they were used for electrochemical studies. These as-obtained QDs have good reproducibility, long-lasting stability, prominent selectivity, and repeatability. It was reported that as-fabricated Au@B-GQDs/GC electrodes can be used as simple and effective sensing platforms for the detection of guanine and adenine in neutral media.

8.3.7 Others

Pejova et al. (2011) studied transport properties of sonochemically synthesized three-dimensional (3D) assemblies of $AgBiS_2$ quantum dots (thin films). The bandgap energy was determined as ∼1.18 eV, which was found to be higher than the optical bandgap of a bulk semiconductor. It may be attributed to 3D confinement effects on the charge carrier motions within individual QDs. Panda et al. (2017) prepared $AgInS_2$ (silver indium sulfide) quantum dots with size ∼1.4 nm by a sonochemical method in 5 min. They used dodecylamine as a capping agent. The bandgap of as-prepared $AgInS_2$ QDs was found to be about 2.15 eV.

Pejova et al. (2020) synthesized quantum nanocrystals of $CuInS_2$ (cubic modification) by a sonochemical route. It was reported that average particle size, size distribution and degree of structural disorder of these $CuInS_2$ can be controlled by adjusting reactor content and exposure to ultrasonic irradiation. It was revealed that bandgap of as-prepared material can also be tuned. As-prepared material can find application in materials in optoelectronics and solar cells based on inorganic semiconductor systems. Zhang et al. (2020) fabricated AgCl quantum dots via ultrasonic method. The average size of AgCl QDs was found to be 2.5 nm. It was reported that as-prepared AgCl QDs exhibited an excellent photocatalytic activity for degradation of rhodamine B and tetracycline under visible light irradiation. It was also revealed that degradation rate of rhodamine B and tetracycline could reach up to 96.6 and 72.2%, respectively in 20 min, which was much higher with AgCl nanoparticles (23 nm) and AgCl nanospheres (114 nm).

Ramalingam et al. (2021) deposited silver quantum dots particles and nanoparticles of magnetite on nanotubes of bismuth in situ doped manganese oxide (Bi-MnOx). It was reported that Ag QDs particles with very fine size

and Fe_3O_4 nanoparticles were incorporated into the Bi-MnOx polymer composite through high power ultrasonication deposition method. It was reported that nanoparticles of silver were spherical in shape with size ranging between 5−15 nm and these were deposited on the Bi-MnOx surfaces (porous). On the other hand, Fe_3O_4 particles (nanorods) were deposited on Bi-MnOx nanotube composite. As-prepared nanoparticle-modified Bi-MnOx composite electrode can be used as electrochemical sensor for hydrogen peroxide detector. It was also revealed that as-prepared Fe_3O_4 and Ag QDs particle-modified Bi-MnoOx nanotubes could remove more than 90% Cr (VI) within 60 min.

8.4 Conclusion

There is a wide range of available methods for synthesizing quantum dots including top-down and bottom-up approaches. Sonochemical synthesis of quantum dots has certain advantages over other conventional methods such as high purity, higher surface area, uniform size distribution, no requirement of additives, and a faster rate. However, it is associated with a disadvantage in that a relatively low yield is obtained, which can be overcome by certain modifications. Quantum dots of various metals, their chalcogenides, and some nonmetals-based QDs have been discussed with their applications. This approach can occupy a prominent position amongst other methods of synthesizing quantum dots in the coming few decades.

9.1 Introduction

Photocatalysis is a branch of chemistry that deals with chemical reactions taking place in the presence of light and a photocatalyst. A photocatalyst is a semiconductor that enhances the rate of reaction by its presence. Thus photocatalysis is a phenomenon, where an electron−hole pair (exciton) is generated on exposing semiconducting materials to light of suitable energy. Thus the chemical reactions that occur in the presence of a semiconductor and light are collectively termed as photocatalytic reactions. Photocatalytic reactions are mainly classified into two categories: (1) homogeneous photocatalysis, where substrate and photocatalyst both exist in the same phase; and (2) heterogeneous photocatalysis, in which substrate and photocatalyst exist in different phases.

Different dyes and some soluble coordination compounds are used as homogeneous photocatalysts, whereas different semiconducting powders are good examples of heterogeneous photocatalysts. The importance of photocatalysis lies in the fact that a photocatalyst provides both an oxidation and reduction environment simultaneously. This field has been extensively reviewed by various researchers (e.g., Fox and Dulay, 1993; Ameta et al., 1999; Chong et al., 2010; Pelaez et al., 2012; Ameta et al., 2013; Ibhadon and Fitzpatrick, 2013; Schneider et al., 2014; Ameta and Ameta, 2016; Zhang et al., 2019; Djurišić et al., 2020; Ren et al., 2021).

Photocatalysis is a main tool in dealing with some major problems of the world such as environmental pollution, wastewater treatment, water splitting for combating energy crises, self-cleaning, antifogging, biomedicals, solar cells, etc.

Thus heterogeneous photocatalysis involves a chain of oxidative and reductive reactions on the surface of the photocatalyst. The energy difference between

Quantum Dots. DOI: https://doi.org/10.1016/B978-0-12-824153-0.00009-4
© 2023 Elsevier Inc. All rights reserved.

the valence band and the conduction band is called the bandgap (Eg). When a photocatalyst is exposed to light of the desired wavelength (sufficient energy, i.e., equal to or more than bandgap), the energy of photons is absorbed by an electron (e^-) of the valence band and it is excited to the conduction band. In this process, a hole (h^+) is created in the valence band. This process leads to the formation of photoexcitation state e^- and h^+ pair. This excited electron is used for reducing an acceptor, while a hole is used for oxidation of donor molecules.

There are some advantages of photocatalysts and these are:

- The catalyst is low cost, nontoxic, and reusable.
- The only requirement for such a reaction is the presence a semiconductor and light.
- The process takes place at ambient conditions.
- The pollutants may be degraded finally to CO_2, H_2O, and other inorganic substances, that is, complete mineralization.

Water is a universal solvent and it is required for the survival of life on this planet. Water is polluted due to an increased utilization in domestic and industrial activities, which poses a special threat of contaminating surface and groundwater. In recent years, advanced oxidation processes (AOPs), particularly photocatalysis, have been applied to treat wastewater problems. This is a green method to oxidize organic contaminants with strong reactive oxidizing radical species like $^{\bullet}OH$, $HOO^{\bullet}$, $O_2^{-\bullet}$, etc. It fulfills the goals of being environmentally friendly and showing sustainable development due to the unique electronic, optical, and structural properties. The important aspect of these nanoscale materials is their large surface area-to-volume ratio and quantum confinement effects, which are necessary for catalysis.

After the discovery of quantum dots (QDs), their potential applications for chemical sensing, bioimaging, drug delivery, and photocatalysis have been tremendously developed. It is due to their excellent aqueous solubility, magnificent electron transfer, and ability to harness light to make full utilization of solar insolation. Green QDs, particularly carbon QDs (CQDs), have received considerable interest in this blooming field due to their nontoxic behavior, greater sustainability, outstanding photostability, and their natural photoluminescence properties. These CQDs also have tunable optical properties and high biocompatibility; as a result, they have a number of applications. The importance of such studies lies in designing efficient photocatalysts, surface modification, charge transfer, and development of ternary photocatalysis. These techniques will significantly increase the photocatalytic activity of semiconductors with wide bandgaps, which can be utilized for solar energy conversion.

9.2 Quantum dots

QDs are semiconductor nanoparticles that exhibit size and composition-dependent optical and electronic (optoelectronic) properties. These are ultrasmall

in terms of size, ranging between 2.0 and 10.0 nm. These can be used in wastewater treatment (removal or degradation of pollutants), hydrogen generation from water (as the fuel of future), reduction of carbon dioxide (putting a check on ever increasing amount of CO_2 in atmosphere, that is, controlling global warming), and converting solar energy into electrical energy (solar cell, drug delivering), etc.

9.3 Wastewater treatment

Industries are regularly increasing the level of manufacture of materials due to the demands of society. These materials include different drugs, dyes, pesticides, etc. These industries release their effluents into the water resources with no or negligible treatment. As a result, water is polluted. Most of the chemicals are quite toxic and some of them are even carcinogenic, and therefore there is a necessity to treat wastewater by any alternate but eco-friendly and effective method. Photocatalysis can degrade most of these pollutants through oxidation because it is one of the techniques involving AOPs (green chemical pathways).

Wahab et al. (2013) compared the photocatalytic properties of TiO_2 and ZnO QDs for oxidation and degradation of acetaldehyde in gaseous phase. It was observed that rate constant for as-prepared ZnO QDs and Degussa P-25 was 8.3×10^{-3} and 1.9×10^{-2} min., respectively about, which was about two times. Their efficiencies were 70% and 92% for Degussa P-25 and ZnO-QDs, respectively in 2 h. It was observed that as-prepared QDs were of 6−7 nm size with wurzite phase.

Quan et al. (2016) prepared quasinoble-metal graphene QDs (GQDs) deposited stannic oxide by just sintering citric acid and SnO_2 together. A redox process between GQDs and SnO_2 generated oxygen vacancy (OV) states somewhere below the conduction band of stannic oxide. These VOs will shift the optical absorption band of SnO_2 towards the visible light region. The GQDs can also effectively increase the charge separation efficiency through noble metal promoting visible light response to some extent. The best performance was exhibited by samples calcinated at 450 °C due to relatively high concentrations of VOs. This study revealed that a combination of defect modulation and noble metal deposition together increased the photocatalytic activity.

Zeng et al. (2016) reported that when graphene oxide QDs (GOQDs) are covalently bonded onto amino modified polyvinylidene fluoride (PVDF) membrane, it resulted into a new type of nanocarbon functionalized membrane with remarkable enhanced antibacterial and antibiofouling properties. An *Escherichia coli* containing water exhibited a decrease in relative flux over GOQDs modified PVDF, which was 23%, and it is significantly lower than with GO-sheet modified PVDF (62%) and pristine PVDF (86%) after 10 h of filtration. The GOQD coating layer effectively inactivated *Staphylococcus aureus* and *E. coli* cells

such that the biofilm could not form a membrane surface. As a result, antimicrobial activity and antibiofouling capability was improved as compared to GO and CNTs modified membranes. This better performance may be due to uniform dispersion and unique structure of GOQDs. A long-term stability and durability was observed in GOQDs modified membrane due to strong covalent interaction between GOQDs and PVDF.

Cheraghizade et al. (2017) synthesized tin sulfide QDs by sonication. It was indicated that SnS and Sn_2S_3 (orthorhombic phase) and SnS_2 (hexagonal phase) wer present and the particle size of these QDs was smaller than other QDs. It was observed that smaller spherical shaped particles were obtained on increasing sonication time. A greater photocatalytic activity was observed for tin sulfide QDs, which were synthesized with longer sonication time. It was reported that solar cell devices constructed using as-prepared tin sulfide QDs exhibited a better performance. This shows that the duration of sonication is an important factor that affects the synthesis process as well as the optical, electrical, photocatalytic, and photovoltaic conversion properties of these QDs.

Xu et al. (2019) fabricated CQDs-N-TiO_{2-x} nanocomposites by decorating CQDs on the Ti^{3+} and nitrogen codoped TiO_2 nanoparticles via a combination of the hydrothermal−calcination method. The formation of N/Ti^{3+} codoping levels and introduction of CQDs in the nanocomposite was also confirmed. It was observed that as-prepared CDs-N-TiO_{2-x} nanocomposite showed increased visible light absorption as well as better charge separation compared to pristine CQDs-TiO_2, TiO_2, N-doped TiO_2 (N-TiO_2), N and Ti^{3+} codoped TiO_2 (N-TiO_{2-x}). As-prepared CQDs-N-TiO_{2-x} nanocomposite exhibited an excellent performance for Cr(VI) reduction in the presence of visible light (Fig. 9.1). It was reported that there was significant increase in the reduction of Cr(VI) on addition of citric acid (hole scavenger). As-prepared CQDs-N-TiO_{2-x} nanocomposite was found to exhibit efficient photocatalytic reduction of Cr(VI) in real samples of wastewater.

There are three important factors that control recovery: draw solution (DS), forward osmosis, and membrane. Doshi and Mungray (2020) reported the synthesis of a novel DS based on CQDs via two different hydrothermal methods (autoclave, A-1; reflux, R-1). They used tulsi (*Ocimum tenuiflorum*) for this purpose. It was found that 5% CQDs prepared by R-1 with 50% glycerol DS (TCQD-G) was found to be effective in inhibiting microbial growth. It was observed that the highest water flux (5.34 LMH) could be achieved with synthetic wastewater (feed solution) using TCQD-G as a DS.

Zhang et al. (2020) studied the use of dual QDs cocatalyst for remediation of organic pollutants. H_2O_2 is considered a green oxidant. They reported that FeOOH QDs/CQDs/g-C_3N_4 composite (FCCN) showed excellent photoactivity for the degradation of oxytetracycline (OTC) under visible light irradiation. The enhanced photoactivity was due to photoexcited electron transfer, where electrons can be quickly utilized by molecular oxygen to form H_2O_2. This results in facilitating the activation of oxygen molecules.

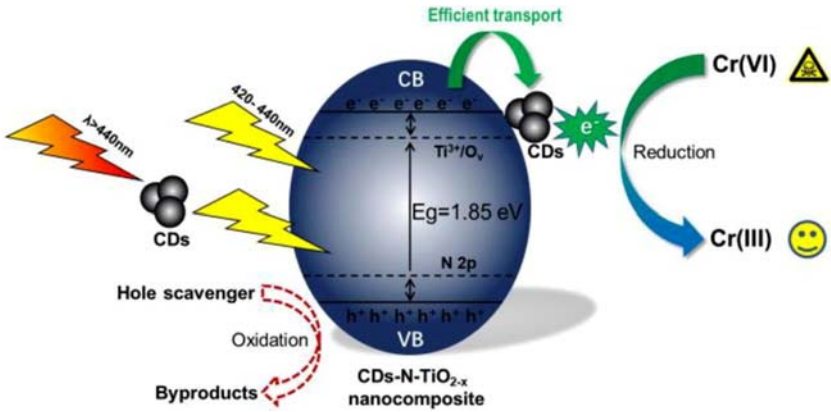

FIGURE 9.1 Photocatalytic reduction of Cr (VI). *Adapted from Xu et al., 2019. Chem. Eng. J., 357, 473–486. With Permission.*

The Fe^{3+} in FeOOH QDs was also reduced to Fe^{2+} by these photoexcited electrons, which react with H_2O_2 to produce the $^{\bullet}OH$ radicals responsible for photodegradation. As a result, surface carrier transfer efficiency (41.01%) was enhanced as compared to only g-C_3N_4 and CQDs/g-C_3N_4 photocatalyst.

9.3.1 Dyes

Different dyes are synthesized and manufactured to fulfill the demand of different color shades by the society, but these are very harmful. If these dyes are accumulated in nearby water resources, this can harm aquatic life, animal life, and human beings on consumption of this polluted water. Thus effluents containing different dyes are to be given photocatalytic treatment, before release to water bodies.

Colloidal oil-soluble Bi_2O_3 QDs were synthesized by Zhang et al. (2010). Water-soluble Bi_2O_3 QDs were produced from oil-soluble QDs through phase transfer by modifying the surface with mercaptopropionic acid. It was reported that water-soluble Bi_2O_3 QDs exhibited outstanding photocatalytic activity for the degradation of methyl orange over a wide range of pH. As-prepared Bi_2O_3 QDs maintained high degradation efficiency even after several cycles. Kusic et al. (2011) reported the use of QDs nanoparticles for treatment of colored wastewater. They used chemical processes for water treatment and disinfection (direct ozonation and direct UV photolysis) for the degradation of colored organic pollutant (reactive azo dye), in the presence of CdSe/ZnS core–shells QDs.

Chen et al. (2013) reported hybrid metal oxide QDs, where Cu_xO and Fe_xO, were anchored on TiO_2 blocks (Cu_xO/TiO_2 and Fe_xO/TiO_2). Their photocatalytic activities were examined by photocatalytic decoloration of methylene blue in the presence of visible light as well as simulated sunlight.

It was observed that these hybrid metal oxide QDs were dispersed uniformly on TiO_2 blocks and both copper and iron were present in mixed valence states (Fe^{2+} and Fe^{3+}; Cu^{+} and Cu^{2+}).

Mansur et al. (2014) reported the fabrication of nanophotocatalysts based on ZnS QDs, which were functionalized with chitosan (CHI) using a green method at room temperature. It was observed that in as-prepared ZnS/CHI nanophotocatalysts (ZnS−CHI) CHI was acting as an effective capping ligand to produce water-soluble ZnS QDs with an average size of 3.8 nm. They selected two model organic pollutants (methylene blue and methyl orange), and these were effectively degraded by ZnS/CHI under UV irradiation. It was also observed that ZnS−CHI nanoconjugates displayed blue photoluminescent behavior, when excited by UV radiation.

Muthulingam et al. (2015) prepared composites containing CQDs/nitrogen-doped ZnO (CQD/N-ZnO) via a one-step method. Three dyes were selected as model pollutants: fluorescein, methylene blue, and malachite green. It was reported that as-prepared CQD/N-ZnO photocatalyst exhibited an increased cohesiveness to degrade all these three dyes within 30−45 min in the presence of daylight. Also, it was found that the composite can be reused because of its antiphotocorrosion behavior furnished by CQDs.

Saud et al. (2015) prepared CQDs/titanium dioxide (CQDs/TiO_2) composite nanofibers through hydrothermal route. It was revealed that the photocatalytic efficiency of as-prepared composite nanofibers was found to be higher than pristine TiO_2 nanofibers for the degradation of methylene blue under visible light irradiation as well as antibacterial properties against *E. coli*. The anchored CQDs can increase light absorption as well as suppressed recombination of photogenerated electron−hole pair resulting in an increase in photocatalytic and antibacterial properties.

Vidhya et al. (2015) reported a modified green synthesis route to prepare pure and starch-capped ZnO (ZnO/starch) QDs. It was observed that a hexagonal crystal structure was present in both pure and ZnO/starch QDs, as evident from XRD data. It was reported that the particles were spherical in shape with a size of 5−10 nm. It was revealed that ZnO/starch QDs showed an increased emission behavior as compared to ZnO QDs. The photocatalytic activity of ZnO QDs was evaluated using the degradation of rhodamine B. Here, it was found that ZnO/starch QDs showed a higher decomposition of dye as compared to pure ZnO QDs.

Fan et al. (2016) synthesized GQDs and polymer-modified GQDs using a hydrothermal method. They used citric acid as a precursor of carbon. The GQDs were modified with polyethylene glycol and polyethylenimine. It was revealed that GQDs were uniform in size (2−5 nm). The photocatalytic activity of these samples was evaluated for the degradation of methylene blue. It was observed that the rate of photocatalytic degradation was found to be in the order:

$$\text{GQDs} > \text{GQDs-PEIs} > \text{GQDs-PEGs}$$

Miao et al. (2016) prepared CQDs embedded in mesoporous TiO_2 materials via a sol−gel method. It was observed that the nanoparticles were randomly packed in inverse surfactant micelles and mesopores are formed by interconnected intraparticles. The photocatalytic activity of as-prepared CQDs/meso-Ti-450 was observed in the degradation of methylene blue. It was observed that photocatalytic activity of the composite material was greatly increased due to the upconversion property and electron withdrawing property of CQDs. The highest photocatalytic activity was obtained by the sample (5% CQDs/meso-Ti-450). It was observed that almost 98% dye was removed while only 10% methylene blue can be degraded by commercial P 25.

Rajabi and Farsi (2016) studied the effect of capping agent on the photocatalytic properties of zinc sulfide QDs. They synthesized ZnS QDs by an aqueous chemical precipitation method using different capping agents (thiourea, 2-mercaptoethanol, and l-cysteine). It was observed that the optical absorption band of ZnS nanostructures also changed with capping agents. As-prepared ZnS QDs were used for photodegradation of crystal violet as a model dye in an alkaline medium with a low concentration of QDs.

Zhang et al. (2016) prepared nitrogen-doped CQDs/TiO_2 (NCQDs/TiO_2) hybrid composites. It was reported that the NCQDs were introduced onto the TiO_2 surface. The photocatalytic activity of as-prepared NCQDs/TiO_2 hybrid composites was evaluated by selecting methylene blue as the target pollutant. It was found that the photodegradation efficiency of dye over 1NCQDs/TiO_2 was about 86.9%, which was much more than pristine TiO_2 (53.8%) The increased photocatalytic activities of NCQDS/TiO_2 hybrid may be due to interfacial transfer of photogenerated charges to NCQDs from the conductive band of TiO_2; leading to effective charge separation in TiO_2.

Anh et al. (2017) fabricated N, S-codoped GQDs (N, S-GQDs) by a hydrothermal route. It can be used for selective and sensitive detection of mercury ions (Hg^{2+}) in water as well as wastewater. It was reported that as-prepared N, S-GQDs were uniform in size with an average particle size of 3.5 ± 0.5 nm. It was reported that doping of nitrogen atoms increased the quantum yield up to 41.9%, whereas sulfur atoms were responsible for better selectivity of Hg^{2+} through strong coordination interaction. It was found that the fluorescence intensity of N, S-GQDs was proportional to Hg^{2+} quenching with a limit of detection of 0.14 nM. As-prepared N, S-GQDs were used for detecting mercuric ions samples of sewage and dye wastewater.

Kumar et al. (2018) synthesized GQDs decorated ZnO nanorods heterojunctions. They evaluated photocatalytic performance of these heterojunctions for the degradation of methylene blue and also carbendazim, a fungicide in the presence of sunlight. It was observed that this heterojunction with 2 wt.% of GQD (ZGQD2) exhibited best photocatalytic degradation (about 95%) of methylene blue and carbendazim as compared to ZnO and GQD in 70 min. Higher photocatalytic activity of these ZnO-GQD heterojunctions may be due to an efficient charge carrier separation, increased light

absorption from UV to visible region, as well as high specific surface area of the ZGQD2 heterojunction.

Qu et al. (2018) prepared CQDs/$KNbO_3$ photocatalyst, via hydrothermal and mixed-calcination methods, and it was a visible light driven composite. They also evaluated the photocatalytic activity of CQDs/$KNbO_3$ composites for the degradation of crystal violet dye along with hydrogen production under visible light (Fig. 9.2). It was reported that CQDs/$KNbO_3$ composites exhibited much higher photocatalytic activity than the $KNbO_3$. This is all due to the presence of CQDs as cocatalyst on $KNbO_3$ particles surface. This formed much more active sites, which can trap electrons; thus inhibiting recombination of photogenerated electron−hole pairs. It was also observed that as-prepared CQDs/$KNbO_3$ can be used again even after four repetitive cycles.

Gao et al. (2019) synthesized CQDs via a hydrothermal method. They used waste larch wood as the raw material. The 3D Bi_2MoO_6 hollow microspheres can be prepared by a mixed solvothermal method without using any surfactants. The Bi_2MoO_6 was used as a matrix and it was doped with CQDs to get a new composite material (CQDs/Bi_2MoO_6). It was observed that methylene blue was degraded by Bi_2MoO_6 hollow microspheres in the presence of visible light. This photocatalytic performance was found to increase when these hollow microspheres were modified with CQDs.

Jat et al. (2019) investigated the photocatalytic degradation of fast green in the presence of visible light using SnO_2-TiO_2. They prepared SnO_2 QDs by a hydrothermal method using stannic chloride (hydrate) as the source of tin. This composite exhibited more photocatalytic activity than titania nanopowder for the degradation of fast green. Karimi et al. (2019) synthesized zinc sulfide QDs by chemical precipitation method under ultrasonic radiation. They used two capping agents, l-cysteine and 2-mercaptoethanol. It was

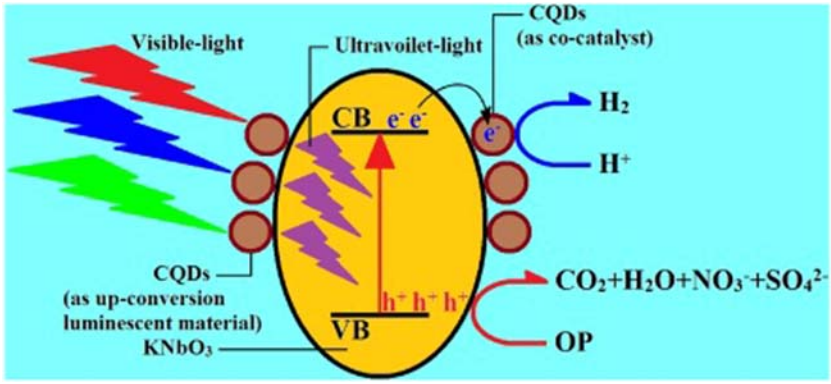

FIGURE 9.2 Photocatalytic hydrogen generation by CQDs/KN composite. *Adapted from Qu et al., 2018. Mol. Catal., 445, doi: 10.1016/j.mcat.2017.11.002. With Permission.*

observed that the as-synthesized QDs were cubic in structure with a particle size less than 10 nm. These QDs were then used for the degradation of crystal violet. It was also revealed that QDs can be reused five times without any significant loss in photocatalytic activity.

Lin et al. (2019) synthesized ternary heterostructure photocatalyst by coanchoring the NCQDs and graphitic carbon nitride QDs (CNQDs) on the surface of $BiVO_4$ microspheres. The as-synthesized $BiVO_4$/CNQDs/NCDs ternary heterostructure was found to exhibit an excellent photocatalytic activity for the degradation of rhodamine B and tetracycline in the presence of visible light as compared to pure $BiVO_4$, $BiVO_4$/NCDs, and $BiVO_4$/CNQDs. The higher photocatalytic activity in this composite may be attributed to an efficient separation and transport of photogenerated charge carriers.

Sharma et al. (2019) reported a template-free sonochemical synthesis of α-Bi_2O_3/C-dots. They used this composite for the degradation of indigo carmine and levofloxacin under visible light (Fig. 9.3). It was reported that α-Bi_2O_3 in the nanocomposite has a monoclinic phase. Its bandgap was found to be 2.49 eV. The as-prepared photocatalyst exhibited higher visible light driven photocatalytic activity for the degradation of indigo carmine (86%) than α-Bi_2O_3 (57%) and levofloxacin (79%) within 2 h. It was confirmed that hydroxyl radicals played a dominant role in the photocatalytic degradation of indigo carmine.

The plasmonic Au nanoparticle (NP)/SnO_2 quantum dot (SQD) (Au/SQD) nanocomposites were prepared by Babu et al. (2019) via a solvothermal method. The photocatalytic activity of as-prepared plasmonic Au/SQD nanocomposites was evaluated for the degradation of rhodamine B. The Au/SQD photocatalyst prepared by using tin chloride (1.0 g), exhibited better dye degradation as compared to pristine SQDs. This increased catalytic performance may be attributed to a shift of the bandgap from the UV to visible region. It was also revealed that synergistic coupling of the semiconductor and metal QDs as well as surface

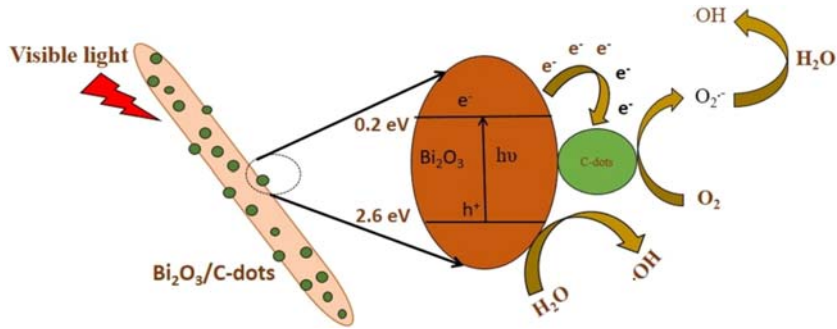

FIGURE 9.3 Photocatalytic degradation of indigo carmine and levofloxacin in the presence of α-Bi_2O_3/C-dot. *Adapted from Sharma et al., 2019. J. Colloid Interf. Sci., 533, 227–237. With Permission.*

plasmon resonance effect of Au NPs played an important role in increasing the catalytic performance.

Xu et al. (2022a) synthesized TiO_2 thin flakes modified with g-C_3N_4 QDs. It was revealed that g-C_3N_4 QDs were in the size of $\sim$10 nm. It was observed that TiO_2 nanoflakes/g-C_3N_4 QDs hybrid exhibited an excellent activity for hydrogen evolution from methanol degradation of rhodamine B (Fig. 9.4).

Jacob et al. (2020) reported the coupling of sulfate reduction with the precipitation of zinc as ZnS QDs at ambient conditions. It was observed that biogenic ZnS QDs had average sizes of 5−7 nm and their formation took 2−4 days of incubation. There was an absorption peak (<325 nm), which may be due to surface plasmon resonance of ZnS QDs and the bandgap of these biogenic ZnS QDs was found to be 3.84 eV. These QDs were successfully used as effective photocatalysts for photoassisted decolorization of Congo red.

Jamila et al. (2020a) fabricated an effective CuO/NCQDs solar photocatalyst using p-type copper oxide, which was modified with NCQDs. A leaf-like morphology for CuO was confirmed for CuO/NCQDs composites by SEM images. It was confirmed that NCQDs are well incorporated on nanoleaves of CuO. As-prepared photocatalyst was used for the degradation of methyl orange (Fig. 9.5). It was observed that this composite catalyst showed higher degradation efficiency as compared to pure CuO nanoleaves, which was attributed to an increased charge separation ability and visible light absorption.

Jamila et al. (2020b) also prepared NCQDs by modifying the surface of graphene oxide (GO) incorporated WO_3 nanosheets. It was observed that the surface of WO_3 nanosheets was modified with morphological defects so that more active sites were available there. As-synthesized ternary composites were used to degrade methyl orange photocatalytically. These ternary

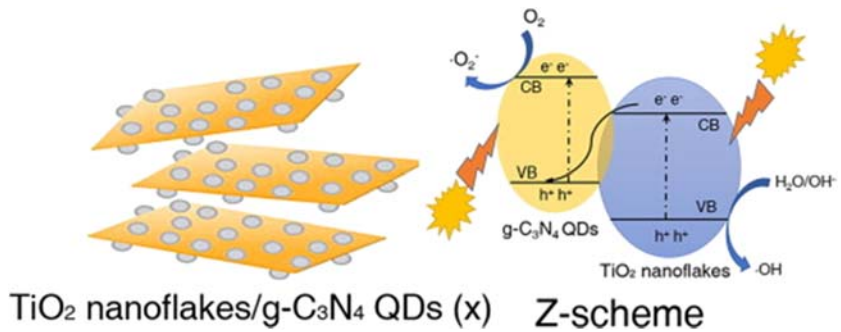

FIGURE 9.4 Use of TiO_2 nanoflakes/g-C_3N_4 for hydrogen generation along with degradation of rhodamine B. *Adapted from Xu et al., 2022a. Chem. Eng. J. 430, doi: 10.1016/j.cej.2021.132861. With Permission.*

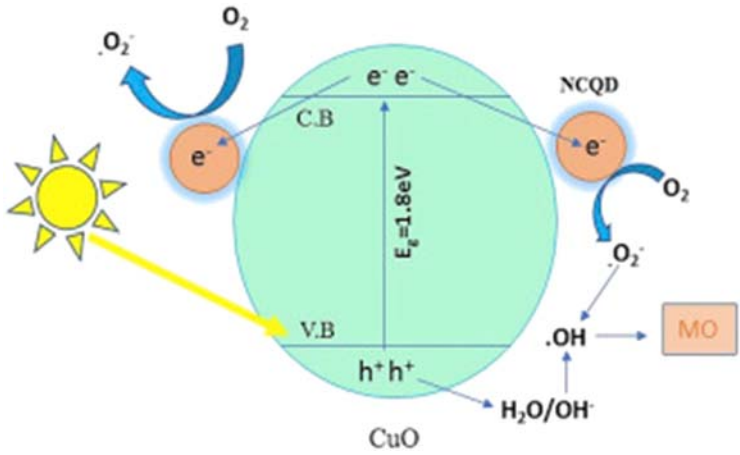

FIGURE 9.5 Photocatalytic degradation of methyl orange on CuO/NCQDs. *Adapted from Jamila et al., 2020. J. Phys. Chem. Solids 138, doi: 10.1016/j.jpcs.2019.109233. With Permission.*

composites exhibited an excellent photocatalytic activity as compared to binary and WO_3 photocatalysts.

The NCQDs were modified with defect-rich g-C_3N_4 (DCN) (NCDs/DCN) by Liu et al. (2020) using an impregnation method. As-prepared NCDs/DCN with narrow bandgap showed excellent visible light absorption and electron transfer ability, which were found useful for photocatalysis of rhodamine B degradation and simultaneous production of H_2. These NCDs/DCN expressed better efficiency in removal of different combination pollutants such as bisphenol A (BPA)/Cr(VI), ofloxacin (OFL)/Cr(VI), and ciprofloxacin (CIP)/Cr (VI) than in a single system. This is due to the synergistic effect between oxidation of organic pollutants and reduction of Cr(VI). An excellent photocatalytic H_2 generation activity and degradation of rhodamine B was there simultaneously with the evolution of H_2 (3.68 μmol h^{-1} g^{-1}) and 100% removal of dye, respectively.

Vatanpour et al. (2020) used GQDs for preparing polyvinyl chloride (PVC) blended matrix. It was then used for the removal of reactive blue 19 dye from wastewater. An improved antifouling performance was also reported by the filtration of bovine serum albumin (BSA) solution. When GQDs were added to the PVC matrix (1 wt.%), it was found that water flux reached 19.1 Lm^{-2} h^{-1}, which was around 56% higher than the unfilled membrane. It was observed that as-prepared PVC membranes have rejection of reactive blue 19 (>96%) and BSA (>98%).

Hui et al. (2021) synthesized heteroatoms-doped CQDs using rice husk as a biowaste precursor. They studied the effects of nitrogen and bismuth doping. They used ethylenediamine and bismuth nitrate pentahydrate as the source of nitrogen and bismuth, respectively. It was observed that these CQDs were spherical in shape with a size of less than 10 nm. The addition

of bismuth nitrate pentahydrate and ethylenediamine tuned the fluorescence intensity and shifted the emission to higher wavelength from the blue to green region. The activity of rice husk derived CQDs (RHCQDs) was examined by photodegradation of methylene blue as well as removal of copper (II). It was revealed that Bi-RHCQDs (5 wt.%) and N-RHCQDs (10 vol.%) exhibited the highest methylene blue degradation performance, 68.91% and 72.16%, respectively. These doped RHCQDs were also tested for removal of copper(II) with 56.23% and 33.13%, efficiency.

Sahu et al. (2021) decorated GO with SnO_2 QDs and used them for the degradation of methylene blue under visible light. It was revealed that about ~94% methylene blue was degraded using only 0.5 mg of GO-SnO_2 catalyst in 30 min. The preparation of GQDs from pyrocatechol has been reported by Mandal et al. (2021) at different pH. The photocatalytic behavior of as-synthesized GQDs was evaluated in the degradation of two dyes, methyl orange and methylene blue, in the presence of visible light irradiation.

Empty fruit bunches by-products of palm oil mill industry containing lignin were used as raw material in the fabrication of sulfur-doped CQDs (SCQDs) by Abd Rani et al. (2021) through a hydrothermal treatment. The SCQDs remained unchanged even after several hours of UV light exposure and also after storage for 8 months, which indicates the excellent stability. The average particle size of as-prepared SCQDs was found to be 2.9 nm. The photocatalytic activity of SCQDs was evaluated for the degradation of crystal violet dye under UV light, which could reach 99.7% degradation in 200 min.

The TiO_2/GQDs nanocomposite was synthesized by Niazi et al. (2021) and used for the degradation of textile dye, reactive black 5 (RB5). It was reported that almost complete (100%) degradation of 50 ppm RB5 could be achieved by TiO_2/GQDs within 30 min under sunlight irradiation. The main active species for the degradation of RB5 was confirmed as surface hydroxyl radicals based on scavenger studies.

Ahlawat et al. (2021) synthesized CQDs via a microwave-assisted method. It was reported that CQDs were small in size (about 2 nm) with spherical shapes. The photocatalytic degradation of rhodamine B was studied in the presence of CQDs and the highest degradation of 99.7% could be achieved under UV light irradiation.

Hatefi et al. (2021a,b) reported that photocatalytic activity was enhanced in electron-rich GQDs with Fe_3O_4/TiO_2 nanocomposites. They could achieve 86.08% removal efficiency of methylene blue, which was more than with TiO_2. The as-synthesized material improved photocatalytic efficiency for the degrading MB under UVA light irradiation compared with merely pure anatase TiO_2.

Two samples of zinc oxide QDs (ZQs) (S_1 and S_2) were synthesized by Mohamed et al. (2021) via a solvothermal method. The crystallite size of these samples, S_1 and S_2, was found to be 8.4 and 9.6 nm, respectively. It

was revealed that the sample S_1 exhibited the best degradation of dianix blue dye. Sharma et al. (2021) synthesized CQDs via a hydrothermal method. They used m-phenylenediamine and l-glutamic acid for this purpose. Then these were combined with nano-TiO_2 to obtain CQDs/TiO_2 composites. It was observed that CQDs/TiO_2 (CT-1) composite with 1:1 molar ratio of l-glutamic acid to TiO_2 exhibited the best degradation efficiency for methyl orange. It was revealed that sample CT-1 can degrade 70.56% of methyl orange, which was almost is 12.7 times higher than that of TiO_2.

The ZQs was synthesized by Mohamed et al. (2022) using a modified precipitation process. The crystallite size of ZQs was found to be 4.4 and 5.3 nm for the ZQ1 and ZQ2 samples, respectively. The photodegradation process of indigo carmine dye ZQ1 reached the highest synthetic levels equal to $1.718 \times 10^{-2}\ s^{-1}$. They tried it on 16 factory effluents samples, and it was observed that it can be used for 10 replication cycles after recovery in the presence of ZQs by sunlight for 2 months.

Smrithi et al. (2022) reported the green synthesis of NCQDs via a hydrothermal technique using extract of *Cucurbita pepo*. The photocatalytic activities of NCQDs were evaluated for the degradation of crystal violet under visible light. They could achieve 99.9% degradation of crystal violet in 3 h in the presence of 1 mL H_2O_2. It was revealed that a prominent role was played by $^{\bullet}OH$ radicals in this degradation.

The black phosphorus QDs (BPQDs) were prepared by Fan et al. (2022) and photocatalytic activity of BPQDs was investigated by selecting indigo carmine as a model dye. It was observed that decolorization efficiency of this dye could reach 98.22% in the presence of sunlight.

Sun et al. (2022) synthesized cerium dioxide QDs modified graphitic carbon nitride. It was reported that CeO_2QDs was dispersed homogeneously on the surface of g-C_3N_4. It was observed that as-prepared CeO_2QDs/g-C_3N_4 exhibited a higher rate for the photodegradation ($0.00985\ min^{-1}$) for rhodamine B, which was found to be that seven times higher than that with single g-C_3N_4 (Fig. 9.6).

9.3.2 Drugs

Pharmaceuticals and personal care products are required by the society and their use is increasing day by day. These are emerging as water contaminants as they can affect the quality of water adversely. This results into a potential harm to water supplies, ecosystem and human health. Photocatalysis can degrade these water pollutants into almost harmless products.

Shi et al. (2015) used CdS QDs modified nitrogen-doped TiO_2 plates (NTP) for decomposition of diclofenac (DCF). They used thiolactic acid as a linker to bind CdS QDs on NTP in situ. This composite NTP/CdS exhibited much higher photocatalytic activity for the degradation of DCF under visible light. It was observed that degradation rate was significantly increased as

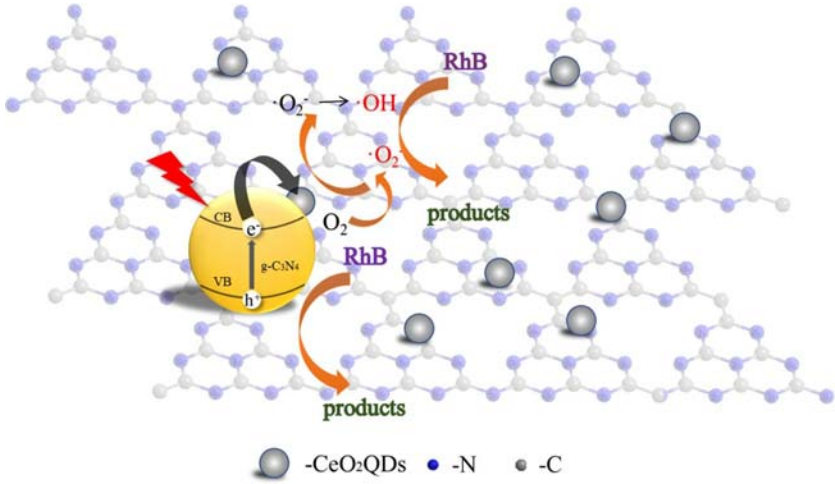

FIGURE 9.6 Photocatalytic degradation of rhodamine B on CeO_2QDs/g-C_3N_4. *Adapted from Sun et al., 2022. Appl. Surf. Sci., 576, doi: 10.1016/j.apsusc.2021.151901. With Permission.*

compared to NTP and CdS, which was about 1.95 and 2.88 times, respectively. The TiO_2 QDs were synthesized by Kaur et al. (2015) via ultrasonic-assisted hydrothermal process. They used as-prepared QDs for photocatalytic degradation of ketorolac tromethamine in the presence of sunlight. It was revealed that ~99% ketorolac tromethamine drug was photodegraded.

Ionic liquid induced strategy was used by Xia et al. (2016) for controlled synthesis of CQDs (CQDs)/BiOX (X = Br, Cl) hybrid nanosheets. They selected three different types of pollutants, such as CIP rhodamine B (RhB), and bisphenol A (BPA) to evaluate the photocatalytic activity of CQDs/BiOX composite nanosheets. The highest photocatalytic activity was observed with sample 3 wt.% CQDs/BiOBr nanosheets for the degradation of CIP, RhB, and BPA under visible light irradiation. It was revealed that are three factors are responsible for enhanced photocatalysis: Lower resistance, high visible light absorbance and high separation efficiency of photoinduced holes and electrons.

Di et al. (2017) prepared NCQDs/$BiPO_4$ composite using ionic liquid assisted solvothermal method. This N-CQDs/$BiPO_4$ exhibited an enhanced photocatalytic activity for the degradation of three antibiotics (CIP, tetracycline and enrofloxacin) under UV irradiation The main active species was found to be superoxide radicals and not hydroxyl radicals. Kaur et al. (2017) synthesized Ag_2O/TiO_2 QDs using pH-mediated precipitation method. It was revealed that as-obtained Ag_2O/TiO_2 QDs were spherical in shape with size ranging between 2−9 nm. As-synthesized composite exhibited significant photocatalytic activity for the degradation of levofloxacin under visible light than TiO_2.

A metal-free composite photocatalyst (GQDs) decorated graphitic carbon nitride nanorods (g-CNNR), was obtained by Yuan et al. (2019) via

hydrothermal technique. The GQDs/g-CNNR exhibited higher photocatalytic activity for removal of antibiotics. It was observed that photocatalytic reaction rate was 2.03 and 3.46 times higher as compared with g-CNNR and pristine graphitic carbon nitride (g-C_3N_4), respectively. It was revealed that this composite show excellent stability and reusability. It was confirmed that photoinduced holes as well as superoxide radicals are main active species in the photocatalytic degradation.

Chen et al. (2019) synthesized CQDs modified potassium titanate nanotubes (CQDs/$K_2Ti_6O_{13}$) via hydrothermal treatment. The successful deposition of CQDs on $K_2Ti_6O_{13}$ photocatalyst was evident from TEM images. The performance of CQDs/$K_2Ti_6O_{13}$ composite was evaluated by degradation of amoxicillin (AMX) under visible light (Fig. 9.7). The photocatalytic activity of CQDs/$K_2Ti_6O_{13}$ hybrid material was found to be higher as compared to neat $K_2Ti_6O_{13}$. It was confirmed that hole (h^+) and hydroxyl radical ($^{\bullet}OH$) played important roles in photocatalytic degradation of AMX.

Jiang et al. (2019) synthesized Fe_3O_4 QDs modified BiOCl/$BiVO_4$ p-n heterojunction. It was observed that 20% Fe_3O_4QDs@BiOCl/$BiVO_4$ p-n heterojunction exhibited an excellent photocatalytic activity for removal of four different broad-spectrum antibiotics in the presence of visible light. The improved photocatalytic performance for the degradation of broad-spectrum antibiotics was mainly attributed to the strong visible light absorption, effective charge carrier mobility, and large specific surface areas. As-fabricated photocatalyst was found stable even after four cycles and it can also be easily separated using an external magnetic field.

Mou et al. (2019) fabricated ultrathin two dimensional (2D) BiOCl/nitrogen-doped GQDs (BiOCl/NGQDs) composites using a hydrothermal process.

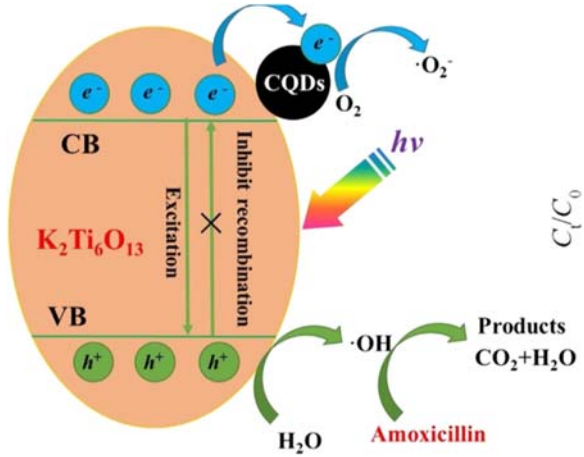

FIGURE 9.7 Photocatalytic degradation of amoxicillin by CQDs/$K_2Ti_6O_{13}$. *Adapted from Chen et al., 2019. Chin. Chem. Lett., 30(6), 1214–1218. With Permission.*

It was observed that BiOCl/NGQDs composites exhibited an increase in both adsorption and photodegradation of CIP as compared to BiOCl. The optimum degradation efficiency of CIP was 82.5% within an hour under visible light, when NGQDs was kept 6.9%, which was much better as compared to BiOCl (34.9%). It was also revealed that this removal efficiency could reach to 95.5% within 5 h.

SCQDs/hollow tubular g-C_3N_4 photocatalyst (HTCN-C) was prepared by Wang et al. (2019) via ultrasonic-assisted method. It was used as catalyst for the degradation of tetracycline (TC) as well as destruction of *E. coli*. It was reported that HTCN-C(2) exhibited an excellent performance for the degrading tetracycline degradation (rate = 0.0293 min^{-1}) and could distract 99.99% *E. coli* under visible destructed light.

Zhao et al. (2019) decorated Co_3O_4 QDs onto phosphorus-doped g-C_3N_4 nanosheets via thermal polymerization method. They used vitamin B_{12} (VB_{12}) as precursor of cobalt and phosphorus mixed with melamine. It was observed that as-prepared sample exhibited the maximum photodegradation efficiency for metronidazole (MTZ), when the sample was prepared with weight ratio of VB12 in precursors at 1%. The efficiency was almost two times better than the removal rate with pure g-C_3N_4. An inhibition was also observed by NO_3^-, Ca^{2+} and HCO_3^-, but Fe^{3+} was found to promote this photodegradation.

The synthesis of self-assembled CQDs and reduced graphene oxide layers modified S@g-C_3N_4/B@g-C_3N_4 (CRSB) (all metal free) was reported by Kumar et al. (2020a). Later, it was used as photocatalyst for the degradation of chloramphenicol (CMP) under visible light and sunlight. It was reported that 99.1% CMP was photodegraded by CRSB in the presence to visible light within 90 min. It was revealed that rate of degradation over CRSB was ten times higher than with g-C_3N_4.

Huang et al. (2020) fabricated up-converted CQDs incorporated goethite (α-FeOOH) nanohybrids (CQDs/α-FeOOH) via hydrolysis method. As-fabricated CQDs/α-FeOOH exhibited excellent degradation of tetracycline (TC), which was almost 3.7 times as compared to α-FeOOH under visible light.

Koe et al. (2020) fabricated a novel photocatalytic membrane by incorporating N,S-CQDs/TiO_2 nanocomposite on polysulfone (PSF) membrane. They used it for photodegradation of DCF in water. The N,S-CQDs/TiO_2 nanocomposites were synthesized with different loadings of N,S-CQDs on TiO_2 nanoparticles. It was observed that N,S-CQDs/TiO_2 (1.5 g) membrane exhibited the best photodegradation performance for DCF removal (62.3%) in the presence of visible light, while TiO_2 membrane showed 3.33% removal only.

Patel et al. (2020) prepared Mn-doped ZnS (Mn:ZnS) QDs through chemical precipitation method. It was observed that as-obtained Mn:ZnS QDs exhibited excellent properties for photodegradation of norfloxacin (NOFX)

in the presence of both UV light and sunlight. These QDs showed excellent stability and reusability up to four consecutive cycles. It was also concluded that these Mn:ZnS QDs could also prove to be useful as efficient as photocatalytic materials in ecological remediation and energy conversion.

Wang et al. (2021) constructed CdS−TiO_2 heterostructure using potato extract as a modifier and a stabilizer. It was revealed that as-prepared CdS−TiO_2 composite exhibited high photocatalytic degradation efficiency with the degradation rate of penicillin (88%). Liu et al. (2021) prepared CQD oxygen-rich titanium dioxide nanosheets (CQD-OTNs) via two-step hydrothermal method. As-prepared composite was used in photodegradation of tetracycline. It was reported that CQD-OTNs could increase the degradation rate of drug to 94.1% within 2 h under visible light irradiation; which was about 2.3 times higher than that with titanium dioxide nanosheets.

Singh et al. (2021) synthesized CdS and CdSe QDs. It was reported that size of the QDs can be controlled by using different mole ratio of water and surfactant. They used thioglycolic acid as capping agent prevent ratio aggregation of QDs The photocatalytic activity of as-synthesized CdSe and CdS QDs was evaluated by selecting 3-aminopyridine as a pollutant.

Wang et al. (2021) used olive leaves as the carbon source to prepare CQDs through hydrothermal treatment. These CQDs were then loaded on the surface of TiO_2 (CQDs/TiO_2 composite). The photocatalytic performance of CQDs/TiO_2 composites was evaluated in the degradation of tetracycline under visible light for 10 min. It was observed that degradation rate of 5% CQDs/TiO_2 could achieve about 81% tetracycline removal.

The silicon-doped CQD were decorated on bismuth molybdate to prepare (1.0SiCQDs/Bi_2MoO_6) nanocomposite by Kumar et al. (2022) via hydrothermal method. It was reported that about 97 and 95% of tetracycline (TC) and of CIP were degraded in 90 min on sunlight exposure.

Xu et al. (2022b) synthesized a series of 0D boron carbon nitride QDs (BCNQDs) modified 2D $Bi_4O_5I_2$ (0D/2D $Bi_4O_5I_2$/BCNQDs) composites. They used these composite for photodegradation of tetracycline (TC) and OTC. It was observed that as-prepared $Bi_4O_5I_2$/BCNQDs composite exhibited highest photocatalytic performance for the degradation of TC and OTC and it was about 4.95 and 2.17 times as compared with $Bi_4O_5I_2$, respectively.

9.3.3 Pesticides

Demand for pesticides, insecticides, weedicides, herbicides, etc. is regularly increasing due to their widespread use in agricultural practices. These are required to safeguard the food grains, foods, vegetables, etc. against any infection or wastage by pest, rodents, etc. and also harm by weeds. These pesticides will reach animals and humans through the food chain causing a number of health problems. It is therefore necessary to treat or degrade these harmful materials. Photocatalysts can play an important role in achieving this object.

Shahnazi et al. (2020) synthesized poly N-isopropylacrylamide (NIPAM) coated MWCNTs/TiO_2 nanocomposite (MWCNTs/TiO_2/TMIP). They selected pendimethalin (PM) herbicide as the target pollutant. This photocatalyst exhibited a higher activity in the degradation of PM (rate constant of 0.0438 min^{-1}) under visible light as compared to other photocatalysts.

The GQDs-ZnO nanocomposites were synthesized by Phophayu et al. (2020). They added GQDs solution into starting precursors during the precipitation. Photocatalytic activity was evaluated for the degradation of glyphosate herbicide over GQDs-ZnO nanocomposites. It was observed that as-prepared GQDs−ZnO nanocomposites exhibited an increased (23% increase) photocatalytic degradation as compared to ZnO.

Xu et al. (2021) fabricated ultrathin CoO/Bi QDs Bi_2MoO_6. It was observed that as-prepared composites exhibited an excellent photocatalytic activity for the removal of diazinon (DZN) (94.2%). They attributed this enhanced photocatalytic activity to the synergistic effect of SPR, ultrathin hollows, oxygen valencies (OVs), and the Z-scheme heterostructure, which will increase visible light absorption and also prevent the recombination of change carriers.

9.3.4 Phenol

Phenols in one or other form are essential at some stages. These also have certain adverse effects on the health of human beings, animals, and aquatic organisms. These phenols can be degraded using an eco-friendly photocatalyst route.

Vertically aligned CdTe−ZnO composite nanorods were fabricated by Liu et al. (2013) from indium tin oxide substrates (ITO). They used a layer-by-layer deposition method formation (CdTe QDs on ZnO nanorod arrays). It was observed that 75% phenol was removed from wastewater in the presence of visible light and composite and 53.2% total organic carbon removal could be achieved within 150 min.

SnO_2 QDs were synthesized by Bhattacharjee and Ahmaruzzaman (2015) via a green biological method using sugar cane juice. The biomolecules of the juice were used as complexing and capping agents and no external agents were required for this purpose. It was observed that as-prepared SnO_2 QDs were spherical in shape with a particle size of ∼3−4.5 nm. They observed a blueshift in the bandgap energy with decreasing particle size, which may be due to quantum confinement effects. The SnO_2 QDs were used for the conversion of *p*-nitrophenol to *p*-aminophenol in the presence of $NaBH_4$ in an aqueous medium. It was reported that 99.5% of *p*-nitrophenol could be reduced in the presence of SnO_2 QDs within an hour.

Kandi et al. (2017) synthesized CdS QDs sensitized self-doped Bi_2MoO_6 via a hydrothermal method. They used glucose as a reducing agent. As-synthesized catalyst was then used to degrade phenol and reduce toxic

Cr(VI) from the aqueous solution. It was reported that 47.5% and 97% degradation of phenol and reduction of Cr(VI), respectively, was obtained using 3% CdS QDs-sensitized self-doped Bi_2MoO_6 in the presence of solar light. Their photostability and reusability was also evaluated and it was observed that this catalyst can be reused for up to five cycles without any significant loss in its activity.

Bajorowicz et al. (2018) comodified CdS quantum dot-decorated $KNbO_3$ composite with Bi_2S_3 QDs by a combination of hydrothermal method with a linker-assisted adsorption route. They used starch and thioglycolic acid as capping agents. It was observed that as-prepared $KNbO_3$-based composites exhibited enhanced photocatalytic performance for the degradation of phenol in an aqueous solution under visible light. It was also reported that the highest photocatalytic performance with better stability were obtained in ternary 30% CdS−5%Bi_2S_3 quantum dot-decorated $KNbO_3$ composite. They also observed catechol, benzoquinone, hydroquinone, and 1,2,4-benzenetriol as the oxidation intermediates of phenol.

Bhatt et al. (2019a) synthesized SnO_2 QDs decorated on TiO_2 nanospheres. Later, they used these composites as photocatalyst for the degradation of 2-nitrophenol. It was found that photocatalytic activity of as-synthesized samples exhibited an efficient degradation of 2-nitrophenol as compared to pure TiO_2 nanospheres.

They also used SnO_2 QDs/TiO_2 nanospheres composite for photocatalytic degradation of picric acid (2,4,6-trinitrophenol) Bhatt et al. (2019b). It is all due to high tunability, high specific surface area, and visible light absorbing ability. It was reported that photocatalytic behavior of as-synthesized samples exhibited better activity compared to only TiO_2 nanospheres.

Hasija et al. (2019) employed a green synthesis approach using bamboo leaves (precursors) for CQDs production via a hydrothermal method. As-fabricated CQDs were then used for the construction of Z-scheme P-doped g-C_3N_4/AgI/ZnO/CQDs (PGCN) heterojunction via immobilization of AgI/ZnO/CQD on graphitic carbon nitride (g-C_3N_4). This composite was then used for the degradation of 2,4-dinitrophenol. The photocatalytic activity of this composite was attributed to electron sink behavior of CQDs. It was reported that this photocatalyst exhibited good stability and recyclability for almost ten cycles.

A solvothermal route was selected by Kumar et al. (2020b) to construct O and S codoped graphitic carbon nitride QDs (OSCNQDs), which were hybridized with Bi_2MoO_6 (BMO). They used these composites for the degradation of aqueous phenol under visible light. As-prepared OSCNQDs/BMO hybrid photocatalyst exhibited almost complete degradation of phenol (98%).

Liang et al. (2020) prepared ZnO composites, which were sensitized by CQDs. They used these composites for the photocatalytic degradation of phenol in the presence of visible light. It was reported that photocatalytic performance of as-prepared ZnO composites (sensitized by CQDs) was

almost 60% higher than that with ZnO. It was also observed that there is good stability and reusability of these composites, as there was no significant change in their activity even after 10 cycles.

9.4 Reduction of carbon dioxide

Scarcity of fossil fuel resources is increasing regularly along with more and more demand for energy in any form. Photocatalytic reduction of carbon dioxide into useful fuels (value-added chemicals) may provide a solution to both these worldwide problems, that is, the problem of the energy crisis and the ever deteriorating environmental quality. Here, photocatalysts have many added advantages. However, some photocatalytic conversion approaches for efficient, economical, and industrialized scalable are to be developed, which can utilize visible and near infrared irradiation.

Wang et al. (2011) sensitized TiO_2 catalysts with PbS QDs. It was observed that PbS QDs enhanced photoreduction rates of CO_2 with TiO_2 almost fivefold as compared to unsensitized TiO_2.

Shao et al. (2017) synthesized ZnO QDs and KNb_3O_8 nanosheets by a hydrothermal technique. They used it for the photocatalytic reduction of CO_2 to methanol. It was observed that the formation rate of pure methanol was only 1257.21 $\mu mol\ g^{-1}\ h^{-1}$, and was found to increase to 1539.77 $\mu mol\ g^{-1}\ h^{-1}$ on deposition of 2 wt.% ZnO QDs on the surface of KNb_3O_8 nanosheets.

The CQDs decorated ultrathin Bi_2WO_6 nanosheets (UBW) were used by Kong et al. (2017) for photoreduction of CO_2 under Vis−NIR irradiation. It was reported that 1CQDs/UBW (1 wt.% CQD content) exhibited higher rate of reduction under visible light irradiation, which has almost 3.1 and 9.5 times enhancement in CH_4 production over UBW and pristine Bi_2WO_6 nanoplatelets (PBW).

ZnO QDs/KNb_3O_8 nanosheets were synthesized by Shao et al. (2017) via a hydrothermal method. The photocatalytic activity of as-prepared materials was evaluated for the photoreduction of CO_2 into formaldehyde under UV light irradiation. The rate with KNb_3O_8 nanosheets was found to be 1257.21 $\mu mol\ g^{-1}\ h^{-1}$, which was increased to 1539.77 $\mu mol\ g^{-1}\ h^{-1}$ on using 2 wt.% ZnO QDs on the surface of KNb_3O_8 nanosheets.

Zubair et al. (2018) reported a photocatalyst composed of graphene-TNT (G-TNT) films and TiO_2 nanotube arrays (TNTs) sensitized with electrodeposited GQDs. It was observed that optimal G-TNT samples could promote the reduction of CO_2 to CH_4 with a rate of 1.98 ppm $cm^{-2}\ h^{-1}$.

Kumar et al. (2019) prepared a hybrid photocatalyst that consisted of a cobalt phthalocyanine tetracarboxylic acid (CoPc-COOH) complex immobilized on organic graphitic carbon nitride. They used triethylamine as a sacrificial electron donor. It was observed that 88.5 μmol (1770 $\mu mol\ g^{-1}$cat) and 59.2 μmol (1184 $\mu mol\ g^{-1}$cat) yield of methanol was obtained (6.5 μmol Co, equivalent to g-C_3N_4/CoPc-COOH) and g-C_3N_4 (50 mg).

A simple complexation−oxidation method was used by Li et al. (2020) to encapsulate CuO QDs in the pores of a metal−organic framework (MOF) of MIL-125(Ti). Then they combined it with g-C_3N_4 to develop a composite photocatalyst, g-C_3N_4/CuO@MIL-125(Ti). It was reported that the photogenerated electrons in MIL-125(Ti) and g-C_3N_4 could be easily transferred to the confined CuO QDs, resulting in enhancement of photocatalytic activity of g-C_3N_4/CuO@MIL-125(Ti) for reducing CO_2 in the presence of water. Use of this photocatalyst could afford CO, methanol, ethanol, and acetaldehyde with yields up to 180.1, 997.2, 1505.7, and 531.5 $\mu mol\ g^{-1}$, respectively.

Indium phosphide (InP) QDs and CdS nanorods were integrated by Do et al. (2020). They used CdS-InP composites for the photoreduction of CO_2 in aqueous solution, where triethanolamine was used as a sacrificial donor. It was observed that photocatalytic activity of the as-synthesized composites was better compared to that of pure CdS alone. The evolution rate of CO over composite was 216 $\mu mol\ h^{-1}\ g^{-1}$ in 3 h.

Qin et al. (2020) synthesized g-C_3N_4 photocatalyst modified by NiS_2 QDs (cocatalyst) via a hydrothermal method. It was observed that this composite exhibited higher activity and stability in the photocatalytic reduction of CO_2. They could achieve the highest evolution rate of CO (10.68 $\mu mol\ h^{-1}\ g^{-1}$) on NSQD/CN-25 catalyst, which was almost 3.88-fold higher compared to g-C_3N_4.

Wang et al. (2020) fabricated 0D/2D heterojunction of $CsPbBr_3$ QDs/Bi_2WO_6 nanosheet (CPB/BWO). Pristine $CsPbBr_3$ has a low catalytic performance due to severe charge recombination. As-prepared CPB/BWO photocatalyst could achieve excellent photocatalytic performance in photocatalytic CO_2 reduction. The total yield of CH_4/CO was 503 $\mu mol\ g^{-1}$, which was nearly 9.5 times higher than that achieved with pristine $CsPbBr_3$.

Que et al. (2021) anchored $FAPbBr_3$ QDs on Ti_3C_2 nanosheets to fabricate $FAPbBr_3$/Ti_3C_2 composite. It was observed that $FAPbBr_3$/Ti_3C_2 composite photocatalyst exhibited an excellent photocatalytic reduction of CO_2. The Ti_3C_2 nanosheet acted as an electron acceptor to promote the rapid separation of excitons and supply specific catalytic sites. It was reported that a consumption rate of 717.18 $\mu mol\ g^{-1}\ h^{-1}$ could be obtained by $FAPbBr_3$/0.2-Ti_3C_2 composite and it was almost 2.08 times the rate of the pristine $FAPbBr_3$ QDs (343.90 $\mu mol\ g^{-1}\ h^{-1}$). This photocatalyst also exhibited good stability during photocatalytic reaction.

A direct Z-scheme 0D/2D heterojunction of CuO QDs/ultrathin CoAl-LDH (CuO/CoAl-u) was prepared by Jiang et al. (2022). It was revealed that 4.5%CuO/CoAl-u heterojunction could achieve yield of CH_3OH as 283.26 $\mu mol\ g^{-1}\ h^{-1}$ by photocatalytic reduction of CO_2.

9.5 Hydrogen production

It has become almost certain that future energy demands cannot be fulfilled by fossil fuel resources because they are reaching a level of

complete exhaustion. Therefore, it is necessary to find an alternate renewable energy source. Nature is playing an indirect role in converting carbon dioxide to carbohydrate (biomass). Here, water is utilized as a reducing agent. Hydrogen can be produced by photosplitting of water in the presence of a photocatalyst and light. It has also been advocated as a fuel of the future creating no pollution, as the final product of combustion is water.

Ge et al. (2012) synthesized CdS quantum dot-coupled graphitic carbon nitride photocatalysts. It was observed that the H_2 evolution rate was 17.27 μmol h^{-1} with CdS QD content (30 wt.%) under visible light irradiation, which was about nine times higher than that with pure g-C_3N_4.

Yu et al. (2014) prepared cobalt sulfide QDs (CoS_x QDs) modified TiO_2 nanoparticles using a precipitation−deposition method. They used cobalt acetate, TiO_2, and sodium sulfide as the precursors of Co, Ti, and S, respectively. The CoS_x QDs act as an effective cocatalyst in photocatalytic H_2 production by TiO_2. It was reported that the amount of CoS_x exhibited an optimum value at about 5% (mole ratio to TiO_2), where the production rate of H_2 could reach 838 μmol h^{-1} g^{-1}, which was 35 times more than with pure TiO_2. Here, ethanol was used as a sacrificial reagent.

Kuang et al. (2016) embedded Au QDs rimous cadmium sulfide nanospheres to synthesize hybrid photocatalysts via a hydrothermal process followed by photoreduction. The rimous cadmium sulfide nanospheres had irregular fissures and a rough surface, which will greatly strengthen their adhesion and interaction with (Au) QDs. It was revealed that the highest photocatalytic activity for hydrogen generation was 601.2 μmol h^{-1} g^{-1} and it was achieved by adjusting the Au mass loading.

Lee et al. (2018) synthesized molybdenum disulfide QDs decorated bismuth sulfide photocatalyst and used them for the generation of hydrogen by photosplitting water. They could achieve the highest hydrogen yield (17.7 mmol g^{-1} h^{-1}) with 0.14MoS_2QD/Bi_2S_3, and this yield was 4.5-fold higher than undoped Bi_2S_3 in the presence of stimulated solar light. As-prepared photocatalyst could achieve a yield of hydrogen (53.6 μmol g^{-1}) in 6 h under NIR irradiation.

Pan et al. (2018) prepared thermally stable and highly dispersed TiO_2 QDs (TiO_2-QDs) in pore channels of SiO_2 foams with large pore size (14−20 nm) using in situ hydrolysis of Ti-alkoxide. It was observed that there was an anchoring effect between the pore-wall of SiO_2 foam and TiO_2-QDs, which resulted in the efficient prohibition of the change in both the TiO_2 phases (anatase to rutile) as well as aggregation of TiO_2-QDs. The crystal size was found to be less than 7 nm. These hybrid photocatalysts show higher efficiency in hydrogen evaluation with a quantum efficiency 17.8% using UV irradiation. It was reported that TiO_2-QDs/SiO_2

photocatalysts exhibited a significant H_2 evolution rate. The outstanding activity of these photocatalysts in hydrogen evolution was due to high anatase crystallinity, short electron-transfer distance, excellent stability of TiO_2-QDs, and uniform dispersity in silica foam.

Sun et al. (2018) adopted two facile synthetic routes for the synthesis of MoS_2 QDs: (1) hydrothermal process and (2) liquid exfoliation strategy. They were used as cocatalyst in photocatalytic hydrogen production under visible light. It was reported that MoS_2 QDs-L (L = liquid exfoliation method) can increase the photocatalytic hydrogen activity of CdS under visible light irradiation. The composite MoS_2 QDs-L/CdS could achieve maximum hydrogen production activity with a rate of 1032.1 $\mu mol\ h^{-1}$ using lactic acid as a sacrificial agent, which was almost 2.7 and 15.4 times more than MoS_2/CdS (383.5 $\mu mol\ h^{-1}$) and CdS (66.9 $\mu mol\ h^{-1}$), respectively.

Luo et al. (2018) fabricated CNQDs on $SnNb_2O_6$ ultrathin nanosheets via a hydrothermal method. It was reported that upconversion behavior of CNQDs in CNQDs/$SnNb_2O_6$ nanocomposites provided the ability of photocatalytic production of H_2 utilizing wavelengths >600 nm.

Yang et al. (2019) reported the development of noble-metal-free catalysts having enhanced photocatalytic activity. The cobalt sulfide QDs g-C_3N_4 nanosheets (Co_3S_4/CNNS) nanocomposites were synthesized by a two-step method, using in situ deposition. It was observed that the particle size of highly dispersed Co_3S_4 QDs was 2−4 nm. These were uniformly fixed on carbon nitride nanosheets (CNNS), which can be a good alternative to noble metals for the improvement of photocatalytic activity of CNNS. It was revealed that Co_3S_4/CNNS-900 had apparent quantum efficiency of the order of 7.85% at 400 nm. It was also observed that the H_2 evolution rate of Co_3S_4/CNNS-900 was found to be 20,536.4 $\mu mol\ g^{-1}\ h^{-1}$, which was about 555 times greater than that with CNNS. The Co_3S_4 QDs were highly dispersed on 2D CNNS, facilitating the formation of more active sites. It also shortened the migration distance of as-generated photogenerated carriers, which finally resulted in an increased photocatalytic performance.

The functionalized carbon nanotubes−titania QDs (FCNT-TQDs) were prepared by Reddy et al. (2020). The CNTs may play a dual role as cocatalyst and photosensitizer to increase light harvesting and reduce the recombination rate of charge carriers. It was observed that the maximum production rate of hydrogen could be obtained up to 54.4 $mmol\ h^{-1}g^{-1}$ by the addition of copper. This rate was 5.4 and 2.5 times higher compared to pristine TiO_2 QDs and FCNT-TQDs composite, respectively.

The nickel (atomically dispersed) in cadmium−zinc sulfide QDs (ZCS QDs) exhibited excellent and stable photocatalytic performance for splitting of water

under sunlight (Su et al., 2020). It was observed that finely tuned Ni atoms dispersed in ZCS QDs exhibited hydrogen production of 18.87 mmol g^{-1}.

Li et al. (2021) anchored small-sized TiO_2 photocatalysts onto large-sized Ti_3C_2-Mxene cocatalysts. A higher hydrogen production rate was observed to be 62.5 μmol with as-prepared photocatalyst, which was about 15.2 times higher than that with TiO_2 (4.1 μmol).

You et al. (2022) prepared (0D/2D) heterojunction nanocomposite [Ag_2S QDs (g-C_3N_4)]. The average particle size of Ag_2S QDs was around 5.8 nm. It was observed that composite (0.5 wt.% Ag_2S QDs) loading could give the highest hydrogen evolution rate of 471.1 μmol g^{-1} h^{-1}.

9.6 Other applications

Cadmium sulfide QDs sensitized mesoporous TiO_2 (photocatalysts) were prepared by Li et al. (2009). First, cadmium oxide was preplanted as crystal seeds in ordered mesoporous titanium dioxide and then CdO was converted to CdS QDs via ion-exchange. As-prepared photocatalyst exhibited an excellent photocatalytic efficiency for oxidation of NO gas in air as well as the degradation of organic compounds in an aqueous medium under visible light.

Bismuth monoxide QDs (average size of 2−5 nm) were prepared by Sun et al. (2017) and then used for the synthesis of ammonia under simulated solar light using photocatalytic reduction of nitrogen. The highest rate (1226 μmol g^{-1} h^{-1}) was achieved for ammonia synthesis without using any cocatalyst or a sacrificial agent. It is about 10^3 times higher than with the Fe-TiO_2 photocatalyst. Zhang et al. (2017) synthesized Pt QDs (2−4 nm) and deposited them on N-doped $(BiO)_2CO_3$ hierarchical superstructures via a hydrothermal method. They used H_2PtCl_6 and ammonium bismuth citrate as precursors. It was reported that as-prepared Pt/N-doped $(BiO)_2CO_3$ catalysts exhibited an enhanced visible light photocatalytic removal of NO removal.

Xie et al. (2018) prepared tin oxide GQDs (SnO_2/GQDs) composite. They used it for the photocatalytic removal of nitric oxide (NO). It was observed that this composite exhibited an enhanced activity compared to SnO_2 only. Visible light response and charge separation efficiency of this composite was increased due to the presence of GQDs in the composite. A series of SnO_2/g-C_3N_4 composites was prepared by Zou et al. (2019). They decorated SnO_2 QDs onto g-C_3N_4 sheets. It was reported that SnO_2/g-C_3N_4 had an excellent response toward visible light and higher ability to inhibit the NO_2 generation.

9.7 Recent developments

Some recent advances are shown in Table 9.1

TABLE 9.1 Some recent applications of quantum dots in photocatalysis.

Quantum dots	Method of synthesis	Application	References
g-C_3N_4 and Ag-g-C_3N_4	Ultrasonication	H_2 production, dye degradation, antimicrobial activity	Mallikarjuna et al. (2021)
SnO_2/$AgVO_3$/g-C_3N_4	Hydrothermal	H_2 production	Koyyada et al. (2021)
Ag/cellulose nanocrystal (CNC)-doped CeO_2	Coprecipitation	Degradation of methylene blue and ciprofloxacin	Ikram et al. (2021)
Covalent organic frameworks (COFs) quantum dots	Solvothermal	Degradation of methyl red, methyl orange and methyl blue	Bahadori et al. (2021)
Carbon dots	Ultrasonication	Degradation of Congo red and methylene blue.	Zaib et al. (2021)
Boron-doped CQD (BCQD)-hybridized g-C_3N_4 homojunction (CN) nanocomposite	Hydrothermal	Degradation of rhodamine B	Phang et al. (2022)
Metal-free boron nitride quantum dots (BNQDs) $BiFeO_3$	Impregnation	Degradation of tetracycline hydrochloride	Balta and Simsek (2021)
Cu-doped carbon quantum dots(CD(Cu)) modified Ni-MOL (CD (Cu)-Ni-MOL)	Hydrothermal	Degradation of Tetracycline	Li et al. (2021)
Silver vanadate quantum dots ($AgVO_3$ QDs)-doped reduced graphene oxide and graphitic carbon nitride nanocomposites modified polyvinylidene fluoride (PVDF) membrane (AgVO3/RGO/C3N4-PVDF)	Fabricated	Degradation of tetracycline, excellent antifouling activity rejection of 97.4% of *Escherichia coli*, self-cleaning capacity	Cui et al. (2022)
Zero-dimensional WO_3 quantum dots on two-dimensional ultrathin $CdIn_2S_2$		Photocatalytic reduction of CO_2	Zhang et al. (2022)

TABLE 9.1 (Continued)

Quantum dots	Method of synthesis	Application	References
Graphitic carbon nitride quantum dots coupled Zr(IV)		Photoreduction of CO_2	Sonowal et al. (2022)
Zero-dimensional (0D) Bi_3TaO_7 (BTO) quantum dots/three-dimensional (3D) onion-ring-like g-C_3N_4 (OR-CN) S-scheme heterojunction	Solvothermal	Photocatalytic evolution of H_2	Shi et al. (2022)
N-doped carbon quantum dots (NCQDs) modified CdS nanocomposite	Hydrothermal	Photocatalytic evolution of H_2	Xu et al. (2022c)

9.8 Conclusion

Photocatalysis makes use of hydroxyl radicals as oxidants; they are considered the strongest oxidants after fluorine. They can degrade the majority of organic pollutants to harmless products such as CO_2, H_2O, and inorganic ions. In other words, it leads to complete mineralization. The ever increasing amount of carbon dioxide is creating havoc in the form of melting glaciers, raising sea level, global warming, etc. which can be controlled by photocatalytic reduction of carbon dioxide to provide some value-added chemicals (synthetic fuels). Use of these fuels will return the same amount of CO_2 to the atmosphere. Thus it can be considered as a short-term loan of CO_2. Another problem of green fuel can be solved by generating hydrogen through photosplitting of water. Hydrogen has a high storage capacity and this fuel will not add any kind of pollution to the atmosphere as water is produced on burning this fuel, which is harmless. Photocatalysis will find a prominent position in solving all these problems in the years to come.

Chapter 10

Application of quantum dots in light-emitting diodes

Anca Armăşelu[1] and Monika Jangid[2]
[1]Department of Electrical Engineering and Applied Physics, Faculty of Electrical Engineering and Computer Science, Transilvania University of Brasov, Brasov, Romania, [2]Department of Chemistry, PAHER University, Udaipur, Rajasthan, India

10.1 Introduction

Quantum dots (QDs) have been extensively investigated in the past few decades owing to their unique properties. QDs are called artificial nanocrystals possessing confinement in all three dimensions with nanometer size that can carry electrons; optical and electrical attributes of QDs can be effectively adjusted by modifying their dimensions, resulting in the emission of specific wavelengths of light (Chen et al., 2020a; Motomura et al., 2020; Singh et al., 2021a).

QDs exhibit numerous unique optical properties such as high photoluminescence (PL) quantum yield (QY), pure and saturated colors, narrow bandwidth, tunable band gap, narrow and symmetric emission, broad and strong absorption (Shirasaki et al., 2013; Pietryga et al., 2016; Bang et al., 2020; Jia et al., 2020; Huang et al., 2020a). Due to their remarkable properties, QDs have found uses in a variety of unusual categories of electronics and optoelectronic tools with potential for application in information displays, solid-state lighting (SSL), biology (Armăşelu et al., 2011a,b), and other structures (Colvin et al., 1994; Ugarte et al., 2012; Nguyen et al., 2019).

Light-emitting diodes (LEDs) reshaped the lighting and display industry and have accomplished considerable developments compared to traditional lighting sources (Zhang et al., 2021a). Exceptional luminescence and charge transport characteristics of QDs show that they are promising alternative emitting materials for the LEDs industry (Colvin et al., 1994; Mattousi et al., 1998; Coe et al., 2002; Kagan et al., 2016; Yang et al., 2019a; Huang et al., 2020b; Bang et al., 2021).

Given the requirements for high resolution and high color saturation, technologies comprising organic LEDs (OLEDs), mini-LEDs (mLEDs), micro-LEDs (μLEDs or μ-LEDs), QD LEDs (QD-LEDs, QD LEDs, or

Quantum Dots. DOI: https://doi.org/10.1016/B978-0-12-824153-0.00010-0
© 2023 Elsevier Inc. All rights reserved.

QLEDs) (Armăşelu, 2017), and laser displays have been produced to substitute liquid crystal displays (LCDs) (Ameta et al., 2019; Ye et al., 2021), μLEDs (Wu et al., 2018; Huang et al., 2019; Wong et al., 2019; Huang et al., 2020b; Bai et al., 2020; Wu et al., 2020; Biwa et al., 2021; Zhuang et al., 2021) and mLEDs (Tan et al., 2018; Huang et al., 2019, 2020b; Sun et al., 2020) and have emerged as next-generation displays providing ultrahigh luminance and long lifetimes.

Ghamsari (2017) reminded that the display industry is interested to mix QD with OLED, noting that an improvement in operation time of OLED device can be realized with the help of QDs. Luo et al. (2018) presented that electroemissive QD displays possess the capability to revolutionize the display industry in the coming years, offering not only the thinness and flexibility of OLED displays, but with the advantages of price, color, and brightness of QDs. High color purity and wide color gamut (WCG) that can be realized using QDs have drawn much attention in display applications (Jiang et al., 2018). The QD-based consumer displays such as LED TVs, tablets, and smartphones offer a reasonable power efficiency and an accessible cost, exhibiting improved competitive edge to OLED technics (Jang, 2018).

A QD display represents a device, which utilizes QDs as a component of panel construction to produce monochromatic red, green, and blue light (Sellers, 2018). They explained that photoemissive QD particles are utilized in LED-backlit LCDs, where a QD layer converts the backlight to give out pure basic colors and electroemissive QD displays constitute a model of novel display based on QD-LEDs (QLED or QD-LED). Liu et al. (2020a) reviewed the newest advances in the implementation of μ-LEDs and QDs in display technology, together with the μ-LED design and QD full-color procedure and provided some insights on the progress of favorable QD film deposition mechanisms, showing the modern uses of QD-based μ-LED displays.

LED-based communication links can be used in both open space and optical interconnect applications. The LEDs based on evolving semiconductor materials are of special importance in the progress of the next-generation data communications (Ren et al., 2021). They are examining the advancement of some LED materials, including the case of colloidal QDs for application in optical communications systems.

This chapter reviews the latest developments on applications of QDs for LEDs, focusing on some key areas such as display, lighting, data communications, agriculture, horticulture, and antimicrobial technology.

10.2 Display and lighting

QDs have a great potential in different optoelectronic applications. They have also found application in LEDs for lighting of different colors due to their tunable fluorescence emission, characteristic broad emission, and high thermal stability. These LEDs are also useful in both SSL and flat-panel

displays. Flexible information displays hold a great promise for future optoelectronic applications, but most of these are fabricated on glass substrates and only a little work has been done LEDs based on flexible substrates.

10.2.1 White light-emitting diodes

Among the optoelectronics applications, the white LED (WLED) exhibits a considerable capability in flat panel displays and SSL (Kim et al., 2016a).

Amorphous silicon QDs (*a-Si* QDs) were grown by Park et al. (2001) in a silicon nitride film via plasma-enhanced chemical vapor deposition. Four types of PL (Red, blue, green, and white) were observed from these *a-Si* QD structures just by control of size of QDs. They fabricated orange LEDs using *a-Si* QDs with average size of 2.0 nm. An external quantum efficiency of 2×10^{-3}% was obtained. It was indicated that LED using *a-Si* QDs embedded in the silicon nitride film was found to be much better than Si-based LEDs in terms of optical and electrical properties.

Park et al. (2004) obtained white light emission from a LEDs. They prepared this diode from polymer/QD nanocomposites using poly(9,9′-dihexylfluorene-2,7-divinylene-*m*-phenylenevinylene-*stat*-*p*-phenylenevinylene) (PDHFPPV) and two kinds of CdSe nanoparticles (NPs) with different particle sizes. It was observed that blue, green, and red emission from the polymer, ~3 nm, and emission from the ~7 nm CdSe, contribute jointly to white emission of the organic−inorganic hybrid device.

Song and Lee (2007a) synthesized (CdSe)ZnS QD−polymethylmethacrylate (PMMA) polymer composite. Then they fabricated QD−polymer composite films. It was observed that 28% (wt./wt.) of PMMA in MMA was desired concentration to produce a film white good quality and the solubility of QDs was also maximized. They fabricated red or green light-emitting (CdSe)ZnS QD−PMMA polymer composite film by combining the red or green light-emitting (CdSe)ZnS dots with PMMA. It was revealed that a white light-emitting device can be prepared by a combination of these green/red light-emitting QD−polymer composites with a blue light-emitting LED (excitation source). It was proposed that as-fabricated QD−polymer composites can be used in full color displays, large-area colored wall-papers, and flexible colored filters.

Jang et al. (2010) used highly luminescent multiply passivated red− and green−light−emitting QDs as color converters in InGaN blue LEDs. They could achieve external quantum efficiencies of 34% and 72%, respectively for these LEDs. As-obtained white QD-LEDs exhibited efficacy of 41 lm W^{-1} and color reproducibility of 100%. Kim et al. (2011) studied $CuInS_2$ QDs as an excellent red emitting source for WLED due to its nontoxic deep red emission. It was revealed that $CuInS_2$ QDs can be synthesized by a one-pot method. Then ZnS shells were formed on QD surfaces so as to

reduce nonradiative recombination on its surface defects. It was observed that core/shell QDs exhibited maximum PL wavelength blue shifts by about 80 nm on increasing intensity more than six times and the QY of as-prepared $CuInS_2$/ZnS QDs was 67%. The transparent and hydrophobic dispersion of QDs in polystyrene was also observed using toluene as codispersing agent. The polystyrene/QD composite was applied on blue LEDs, which exhibited luminous efficacy (LE) of 10.7 lm W^{-1}.

A large-scale synthesis of InP/ZnS core/shell nanocrystal QDs was reported by Kim et al. (2012) using a customized hybrid flow reactor. They synthesized InP cores and InP/ZnS core/shell QDs successively in the hybrid reactor in one-step process only. The flow rate of the solutions was kept typically 1 mL min^{-1} in the reactor, which is about hundred times larger than as kept in conventional microfluidic reactors. The flow rate as well as crystal growth temperature were controlled to synthesize high-quality InP/ZnS QDs. It was revealed that high-quality InP/ZnS QDs (bluish green to red) were obtained and these core/shell QDs could be incorporated into WLEDs devices to improve performance of color rendering.

Song et al. (2012) reported the synthesis of Cu−In−Ga−S (CIGS) QDs. They applied these QDs for WLED with variation of In:Ga ratios. It was found that band gap and emission energies of as-prepared CIGS QDs were higher an increasing Ga contents. It was observed that ZnS shell-capped QDs of the CIGS/ZnS core−shell emitted tunable wavelengths (520−578 nm) with an excellent PL QY of 72%−83%. They reported high LEs of 69.1−75.0 lm W^{-1}, when highly fluorescent CIGS/ZnS QDs as color converters with a blue-emitting LED were combined with efficient white QD-based LEDs. A white QD-LED was also fabricated by blending of two kinds of CIGS/ZnS QDs, which exhibited enhanced color rendering property.

A simple solution method was used by Son et al. (2012) to prepare emissive hybrid QDs, which consists of a ZnO core wrapped in a shell of single-layer graphene. Then these QDs were used to make a WLEDs with a brightness of 798 cd m^{-2}. White emission could also be achieved by combining these QDs with some other emissive materials in a multilayer LEDs.

The color rendering index (CRI) of YAG:Ce-based WLEDs is poor. The core/shell/shell CdSe/CdS/ZnS QDs were synthesized by Shen et al. (2012) and blended into nano-YAG:Ce^{3+} phosphors to improve this index. They obtained a WLED with a combination of blue LED (with the blends of nano-YAG phosphors) and orange- and red-emission QDs in the weight ratio (1:1:1). It was revealed that as-fabricated WLEDs exhibited excellent white light with luminescent efficiency of 82.5 lm W^{-1}.

Song et al. (2013) reported the synthesis of two bright noncadmium QDs of orange (583 nm)-emitting $CuInS_2$ (CIS)/ZnS and green (512 nm)-emitting InP/ZnS core/shell. These were applied for fabrication of SSL devices. It was obtained that spectral overlap between absorptions from both emissions from InGaN-based blue LED chip and QDs was excellent. There was an

efficient downconversion of blue-to-QD emission for the generation of white light by dispensing sequentially InP/ZnS QDs on top of CIS/ZnS within epoxy resin. It was revealed that white QD-LED generated a white light with high quality having a high CRI of 90 and a warm color temperature of 3803K.

Erdem and Volkan (2013) presented that on using QDs in color-conversion LEDs, it is possible to simultaneously achieve remarkable color rendition of the illuminated objects together with an excellent spectral overlap between the emission spectrum of the tool and the sensitivity of the human eye, in addition to a warm white color, unlike other standard sources such as phosphor-based LEDs. They reviewed some modern evolutions in quantum-dot-integrated WLEDs (QD-WLEDs) based on color conversion.

Kubendhiran et al. (2019) reported in a review that WLEDs are an excellent alternative to fluorescent tubes and classical light bulbs in most lighting uses because WLEDs have greater operating lifetimes and important energy savings compared to traditional incandescent light bulbs. They noticed that at the moment there are different types of QD-WLEDs that show these kinds of benefits.

Roy et al. (2014) prepared graphene QDs (GQDs) using plant leaf extracts of Fenugreek (*Trigonella foenum-graecum*) and Neem (*Azadirachta indica*) via a hydrothermal method. They did not use any passivizing, reducing agents or organic solvents. It was reported that the average sizes of the GQDs from Fenugreek (F-GQDs) and Neem (N-GQDs) were 7 and 5 nm, respectively. F-GQDs and N-GQDs exhibited high QYs of 38.9% and 41.2%, respectively. It was revealed that as-prepared GQDs can be utilized to prepare a white light converting cap based on the red-green-blue color mixing method.

The green red Zn−Cu−In−S (ZCIS) and Zn−Ag−In−S (ZAIS)core/shell-like alloyed QDs were synthesized by Yoon et al. (2015) via a hot-injection method. They obtained tunability of red ZCIS and green ZAIS QDs by choosing a high temperature multiple alloyed reaction and low temperature core growth. It was observed that the alloyed red ZCIS and green ZAIS QDs could reach PL QYs of 0.53 and 0.61, respectively was also carried out by them. Practical realization of white downconverted LEDs (DC-LEDs). They also characterized based on CRI, LE, vision & color performance and color quality scale (CQS) of white DC-LEDs incorporated with red ZCIS and green ZAIS QDs. It was reported that tricolor white DC-LED using red-emitting ZCIS core/shell-like alloyed QDs exhibited a moderate LE 31.2 lm W^{-1} with ultrahigh color qualities CRI and CQS as 97and 94, respectively.

Kang et al. (2015) synthesized cadmium-free and water soluble $AgInS_2$/ZnS core/shell QDs. These QD powders exhibited bright orange, yellow, and orange-red luminescence in presence of UV light depending upon Ag/In ratio and PL QYs could reach as high as 57, 50.5, and 52%, respectively. They

obtained warm-WLEDs by a combination of orange-emitting QDs with blue InGaN chip having LE of 39.85 lm W^{-1} and CRI of 71.

Zhang et al. (2018a) synthesized all-inorganic halide perovskite nanocrystals. They used hot-injection method and anion exchange reaction to obtain NPs in the range of 15−40 nm and whole visible light region (410−700 nm). They also constructed a WLED by stacking $CsPbBr_3$ QDs-ethyl acetate composite film and $CaSrAlN_3:Eu^{2+}$-poly (methyl methacrylate) composite film on the blue LED chip. This displayed the ideal white light. It was reported that although WLED is not stable at higher operation current, but it can smoothly work under a lower operation current. Shen et al. (2018) fabricated an efficient flexible white QLED with mixed green, red, and blue QDs as emitters. It was reported that as-prepared flexible white QLED exhibited pure white light emission with brightness of up to 3554 cd m^{-2} and current efficiency of 10.5 cd A^{-1}.

Chen et al. (2018) fabricated silica-wrapped Mn-doped $CsPbCl_3$ QDs with improved operational stability (Fig. 10.1). They hydrolyzed (3-aminopropyl) triethoxysilane for this purpose. They could achieve high PL QY (55.4%) for the $CsPbMnCl_3@SiO_2$ composite. It was reported that wrapping by silica can protect these perovskite QDs from any damage by humidity and temperature. They prepared WLED devices by mixing of green $CsPbBr_3$ QDs and orange-red $CsPbMnCl_3@SiO_2$ composites, which exhibited high LE (77.59 lm W^{-1}) and CRI (82). It was also revealed that electroluminescence spectrum showed almost no variation even after 24 h operation.

Cesium-lead-halide perovskite QDs (PQDs) have excellent superior optical and electronic properties and therefore, these are considered potential materials for various optoelectronic devices. Yang et al. (2019c) developed to hydrolysis encapsulation method by embed PQDs into mesoporous polystyrene microspheres (MPMs), which was followed by silica shell covering process. It generated luminescent PQDs/MPMs@SiO_2 hybrid microspheres with excellent stability. It was reported that as-obtained $CsPbBr_3$-PQDs/MPMs@SiO_2 hybrid microspheres show a high PL QY (84%). As-prepared hybrid microspheres exhibited good chemical/physical stability seven under harsh conditions of environments, particularly acid/alkali solution, deionized water, anion-exchange reactions, isopropanol, and heating. It was also revealed that about 48% proportion of the initial fluorescence intensity is there, even after a quite long storage period of 30 days with water. It was also observed that WLED are achieved by mixing green $CsPbBr_3$-PQDs/MPMs@SiO_2 microspheres with red commercial phosphors on a blue chip with a high power efficiency (81 lm W^{-1}) and good electroluminescence stability.

Sadeghi et al. (2019) optimized the QY of magic-sized CdSe QDs up to 22% through controlling parameters of synthesis without shelling or posttreatment. They integrated them in liquid-state on blue LED so as to prevent the efficiency drop due to host-material effect. It was revealed that

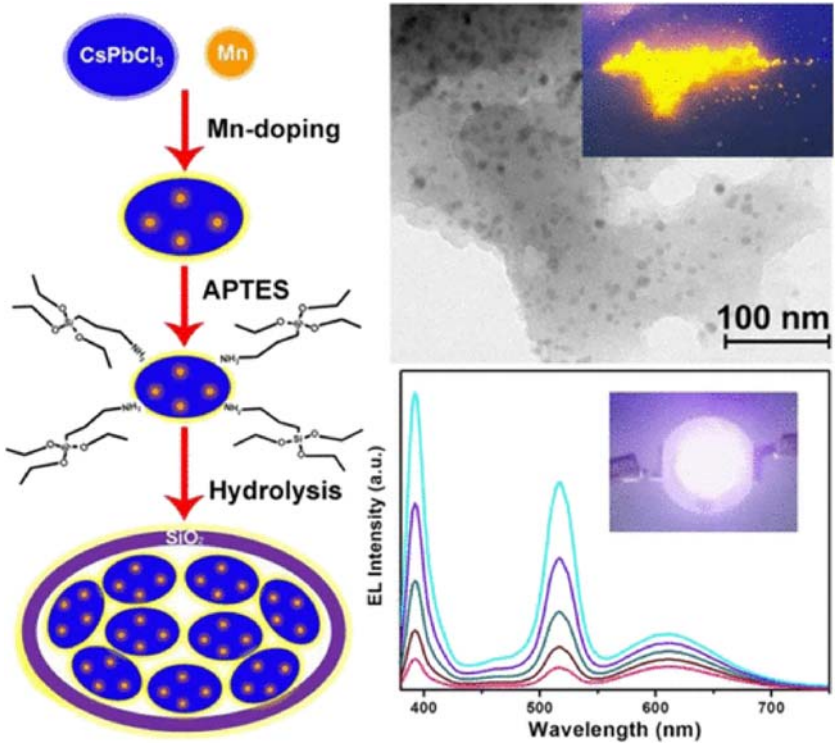

FIGURE 10.1 Fabrication of silica-wrapped Mn-doped $CsPbCl_3$ QDs for LED application. *Adapted from Chen et al., 2018. ACS Appl. Mater. Interfaces,10(50), 43978–43986. With Permission.*

as-prepared WLEDs showed color-rendering index of 89 and LE of 11.7 lmW^{-1}.

Yin et al. (2019) fabricated yellow-green emitting GQDs using low-cost as well as eco-friendly method. As-obtained GQDs were cast in UV-curable siloxane and a polymer film to obtain excellent monodispersity properties and better optical transparency through just adjusting thickness and the concentration of the color convert matrix, so as to achieve tunable color temperatures (3196K−10 870K) of the GQD-based WLEDs. Using the fluorescent polymeric matrix in WLEDs, good quality emission and gratifying stability could be obtained. It was also indicated that this technology has a great potential for applications in high-end lighting.

The synthesis of $CH_3NH_3Pb_{1-x}Mn_xI_3$ PQDs (where manganese is substituted at sites of lead) was reported by Singh et al. (2019). It was observed that these QDs exhibited strong color tunability ranging from red to orange,

when concentration of Mn^{2+} was varied from 0 to 60%. A high external PL QY (98%) was observed for unsubstituted $CH_3NH_3PbI_3$. They developed a WLED using $CH_3NH_3Pb_{1-x}Mn_xI_3$ QDs with green QDs on a blue LED chip.

Yang et al. (2019b) developed a novel package structure to prepare QD-WLEDs using dip-coating red and green QDs/polyurethane composites into TV lens and combine them with a blue LED to form white light. They demonstrated that the in-lens technique has high stability and that a 32-inch prototype LCD TV possesses a WCG of 108% under the National Television Systems Committee standard with this in-lens encapsulation construction.

Perikala and Bhardwaj (2021) reported that QD-WLEDs use diverse colors (red, blue, and green), emitting QDs to achieve white light. They communicated an open air atmosphere synthesis of highly luminescent single system white light-emitting carbon dots (CDs). It was revealed that CDs have been embedded in polydimethylsiloxane (PDSM) polymer and as-produced CD-PDMS phosphor indicated exceptional CRI $\sim$96; the maximal communicated so far with Commission Internationale de l'Eclairage coordinates (0.31, 0.33), which are very similar to pure white light. This research establishes a scaffold for the uses of CD-phosphor-based WLEDs in lighting systems.

The influence of the pore structure of SBA-15 particle was observed by Li et al. (2020) on light emission from inner adsorbed QDs and outer LEDs chips. It is was found that the particle features of a high refractive index, comparable feature size of pore structure, and lower amount of QD adsorption help with QD light extraction, demonstrating a mechanism to suppress QD light propagating through pores and thus reducing the reabsorption loss. Then they developed highly efficient QD WLEDs by wet-mixing QD/SBA-15 NPs. It was observed that as-fabricated LEDs exhibited a record LE of 206.8 lm W^{-1} for WLEDs by integration of green−red QD and green QDs color convertors with improved stability.

Chen et al. (2020b) could obtain uniform blue-green emissive GQDs and modified efficient orange-emitting GQDs (D-GQDs). These QDs were derived from fullerene under acid-free conditions. As-prepared D-GQDs exhibited excellent conversion efficiency with QY of 52.4% at an emission peak of 617 nm. These GQDs and D-GQDs were blended with a polymer; poly(vinyl alcohol) to prepare photoluminescent films (transparent) with excellent flexibility and white emission property. Hu et al. (2020) developed composite orange-red QDs (composite-QDs) by mixing red QDs (R-QDs) and CdSe/ZnS-based orange QDs (O-QDs). It was reported that optimized composite-QDs can improve the CRI of the WLED as compared to monochromatic QDs.

A simple method was developed by Rad et al. (2021) to prepare white light emissive diodes. These are based on colloidal solutions of carbon QDs (CQDs) and $CsPbI_3$ perovskite (PQDs). It was reported that a right combination generates emission across the complete visible spectrum on excitation

by UV light. It was observed that white light emission of the final films provided high and stable CRI (92%). It was also revealed that a mixture can be obtained emitting the cold, neutral, and warm white lights by changing concentration of $CsPbI_3$ QDs for indoor lighting applications. The syntheses of these materials are also low cost and scalable. The colloidal mixture of CQDs and $CsPbI_3$ PQDs shows a facile deposition for LED application, which exhibited white electroluminescence, indicating that both these QDs are stable during LED operation. It was revealed that the PL QY of as-prepared colloidal mixtures was higher (up to 75%) than single white emitters, which indicates a great potential for white emission with tunable properties.

Chen et al. (2021) used Zn doped CdS QD with ZnS shell together with green light emission phosphor. It was observed that degradation of LEDs on degradation of QDs can limit its practical applications, if used for a longer time. There was a reduction in intensity as well as a blue shift of the emitted wavelength from the white light was also observed during degradation. There were three stages of degradation and there are:

1. An enhancement state, where light intensity was increased.
2. It was followed by a rapid degradation stage, where light intensity rapidly decreases, and
3. Slower degradation stage, where the degradation rate of light intensity slows down and goes on decreasing.

The degradation of LEDs was attributed to degradation of CdS core structure, which started with oxidation of sulfur vacancy of CdS QDs by the closely available oxygen atoms. This was all due to imperfection caused in ZnS protective coating around the QDs on explosive to blue light. It was indicated that oxidation transformed CdS into CdO in the initial stage where as $CdSO_4$ is formed via some intermediate processes in final stage.

Zhang et al. (2021b) synthesized green, blue, orange-red, and yellow−green carbon QDs doped with some heteroatoms (Fig. 10.2). They showed emission peaks at 495, 435, 595, and 525 nm with high PL QY (88.9%). A WLED was fabricated with high CRI of 90.8.

10.2.2 Blue light-emitting diodes

In recent years, significant advances have been achieved in the red and green PQDs-based LEDs. However, the performances of the blue perovskite LEDs are still seriously lagging behind that of the green and red counterparts. The visualization of accurate color information using QDs has been explored for decades, and commercial products employing environment friendly materials are currently available. However, next-generation electroluminescent displays based on QDs require the development of an efficient and stable cadmium-free blue light-emitting device, which has remained a

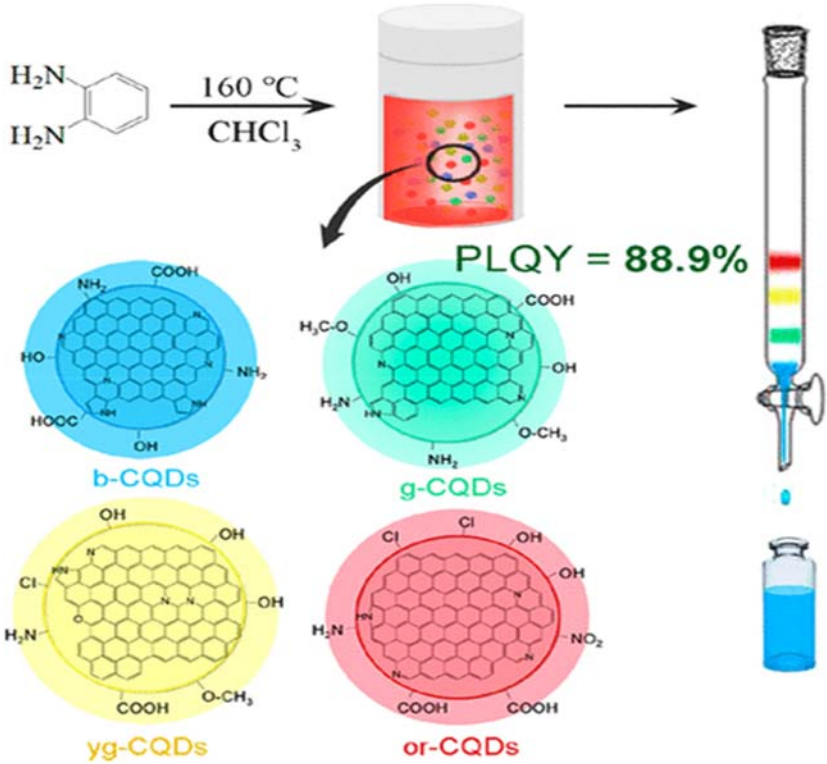

FIGURE 10.2 Synthesis of different colored carbon quantum dots doped with heteroatoms. *Adapted from Zhang et al. J. Phys. Chem. Lett.;12 (37), 8939−8946, 2021. With Permission.*

challenge because of the inferior photophysical properties of blue light-emitting materials.

Realizing of full-color quantum-dot LEDs display remains a challenge because of the poor stability of the blue quantum-dot and the immature inkjet-printing color patterning technology. For colloidal QD QD-LEDs, blue emissive device has always been inferior to green and red counterparts with respect to device efficiency, primarily because blue QDs possess inherently unfavorable energy levels relative to green and red ones, rendering hole injection to blue QDs from neighboring hole transport layer (HTL) inefficient.

Arakawa et al. (2000) have grown InGaN self-assembled QDs on a GaN epitaxial layer via atmospheric-pressure metalorganic chemical vapor deposition. The average diameter of QDs was found to be 8.4 nm. It was also observed that InGaN QDs could be formed even after 10 QD layers were stacked and as a result, the total QD density increased. Luk et al. (2012) fabricated a GQD−agar composite. As-prepared composite exhibited an

excellent optical stability, but no luminescence quenching. This composite was applied successfully as a color converting material to achieve white light emission in blue LEDs. It was reported that light conversion efficiency and LE of the WLED were 61.1% and 42.2 lm W^{-1}, respectively.

It was reported that deep-blue, high color purity electroluminescence was observed in an inverted light-emitting device using nontoxic ZnSe/ZnS core/shell QDs as the emitter (Ji et al., 2013). As-prepared device exhibited a peak at 441 nm. It was observed that current efficiency and maximum luminance could reach 0.51 cdA^{-1} and 1170 cd m^{-2}, respectively. A high performances could be achieved using a ZnO nanoparticle based electron-transporting layer, which can assist in efficient electron injection into ZnSe/ZnS QDs. It was calculated that these efficient deep-blue QD-LEDs can find application in full-color panel displays and QD-based lighting sources.

Lee et al. (2013) synthesized blue CdZnS/ZnS core/shell QDs. It was reported that as-prepared QDs exhibited high PL QY (98%), and high stability. All these solution−processed blue QD-LEDs (multilayered), consisted of HTL of poly(9-vinlycarbazole), electron transport layer of ZnO NPs, and an emissive layer of CdZnS/ZnS QDs. This as-fabricated device exhibited a maximum luminance (2624 cdm^{-2}), external quantum efficiency (7.1%), and LE of 2.2 cdA^{-1}.

Biswas et al. (2016) embedded GQDs into synthesized Amoc (*N*-anthracenemethyloxycarbonyl) capped aromatic amino acid based units. These QDs exhibited blue emission under UV irradiation at a wavelength of 365 nm. It was reported that quenching in emission spectra revealed that there are strong $\pi-\pi$ stacking interactions within Amoc-amino acids and aromatic GQDs. It was also revealed that self-healing properties and thixotropic nature of as-prepared hydrogels can be tuned by introduction of GQDs.

Bharathi et al. (2017) reported the preparation of micron-sized sheets by interconnecting GQDs (GQDs solid sheets) with intrinsic absorption and emission properties. It was observed that metal atoms interconnecting GQDs in hydrothermal growth process, induced some semiconducting behavior in these GQD solid sheets. As-prepared GQDs exhibit a 36% PL QY in the blue region (440 nm). Wang et al. (2017) synthesized highly−efficient blue CdSe/ZnS QDs with emission peak ($>$ 460 nm) with the object to protect human eyes from the harmful effect of short-wavelength light. They fabricated QLEDs based on as-prepared blue QDs and optimized ZnO NPs. It was revealed that using small-size of ZnO NPs, a maximum external quantum efficiency (19.8%) and current efficiency (14.1 cd A^{-1}) for QLEDs were observed. It was proposed that color saturation blue QLEDs have a great potential for use in next-generation full-color displays.

Yuan et al. (2017) synthesized multicolor band gap fluorescent carbon QDs (MCBF-CQDs) via a solvothermal method. The as-prepared QDs have blue to red color with high QY (75%). It was observed that maximum

luminance of as-prepared blue LEDs could reach 136 cd m^{-2}. Lin et al. (2018) synthesized blue nonblinking (> 98% "on" time) ZnCdSe/ZnS//ZnS QDs (Fig. 10.3). The absolute fluorescence QY was found to be 92% ($\lambda_{peak} = 472$ nm). It was reported that these bright nonblinking ZnCdSe/ZnS//ZnS core/shell QDs exhibited not only good tunability in the blue-cyan range (450−495 nm) but also high absolute PL quality yield, but excellent chemical and photochemical stability also.

Wang et al. (2019) synthesized four surface-modified (positively charged metal NPs) with different localized surface plasmon resonance wavelengths and then linked with red-emitting colloidal CdZnSeS/ZnS QDs (negatively charged) on the top surface of a blue-emitting InGaN/GaN quantum well (QW) LEDs. There is strong surface plasmon coupling due to short distance of NP and QD in NP-QD linkage; thus enhancing absorption and emission. A stronger QD excitation was also observed. All the factors together resulted in an increase of color conversion efficiency of the QDs.

Kim et al. (2020) reported the synthesis of ZnSe-based blue light-emitting QDs with a QY of unity. They observed that zinc chloride and hydrofluoric acid additives were found effective in increasing luminescence efficiency. It was anticipated that these efficient and stable blue QD light-emitting devices can find potential application in development of electroluminescent full-color displays.

Pan et al. (2020) developed Ni^{2+} ion-doped $CsPbCl_xBr_{3-x}$ PQDs via supersaturated recrystallization synthesis. It was simultaneously realized that the doping of various concentrations of Ni^{2+} cations modulating the Cl/Br element ratios by introducing different amounts of $NiCl_2$ solution in the reaction medium. It was reported that emission wavelength of Ni^{2+} ion-doped $CsPbCl_xBr_{3-x}$ QDs shifted from 508 to 432 nm. It was observed that blue

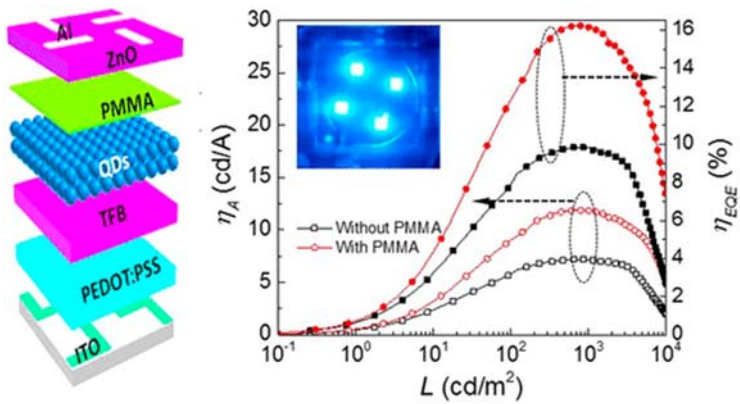

FIGURE 10.3 Luminescence efficiency of blue LEDs based on high quality nonblinking QDs. *Adapted from Lin et al., 2018. ACS Photonics, 5 (3), 939−946. With Permission.*

emission (470 nm) with PL QY 89% was achieved in 2.5% Ni^{2+} ion-doped $CsPbCl_{0.99}Br_{2.01}$ QDs, which was almost three times more than that of undoped $CsPbClBr_2$ QDs. It was revealed that external quantum efficiency of 2.4% could be achieved along with maximum luminance of 612 cd m^{-2}, which is highest amongst other blue-emitting PQD-based LED reported earlier.

Zhang et al. (2020) developed a yellow quantum-dot LED of stacking with a blue organic multifunctional tandem LED using an indium−zinc oxide intermediate connecting electrode. It was reported that as-fabricated tandem LED was full-color-tunable and it can emit green, red, and blue colors (primary color) as well as other arbitrary colors. It was revealed that this tandem LED can emit efficient white light with brightness (107000 cd m^{-2}) and maximum external quantum efficiency (26.02%). It was suggested that white light-emission and multi-functionality of full-color-tunability could find a great potential application in both solid-state lighting and full-color-display.

10.2.3 Red light-emitting diodes

Taylor et al. (2007) used a hybrid layer of poly(2-methoxy,5(2-ethylhexyloxy)-*p*-phenylene vinylene) (MEH-PPV) and CdSe QDs to convert the light emitted by electroluminescent ZnS phosphor into red light. It was revealed that emission wavelength of the display was related directly to the emission of CdSe QDs. It was observed that thin film electroluminescent displays have a potential to increase its color spectrum on integrating QDs.

Song and Lee (2007b) prepared core−shell (CdSe)ZnSe QDs by colloidal chemical synthesis and surface-passivation. They coated a core CdSe with a larger-band gap material ZnSe. As-prepared (CdSe)ZnSe QDs played a role of color conversion center (QDs nanophosphors). The red light-emitting hybrid devices were fabricated consisting of (CdSe)ZnSe QDs and a near-UV GaN LED. They also tested the possibility of using (CdSe)ZnSe QDs as red nanophosphors for UV excitation. It was indicated that (CdSe)ZnSe QDs are quite promising red nanophosphors for NUV excitation. The red LED based on these QDs and a NUV excitation source has proved to be an efficient hybrid device with good luminance.

Stouwdam and Janssen (2008) studied ZnO nanocrystals as an electron injection layer for red, green, and blue LEDs based on core−shell CdSe/ZnS QDs. The deposition of ZnO nanocrystals from isopropanol permits fabrication of multilayer QD-LEDs that include both hole and electron transport layers by simple solution processing. The ZnO nanocrystals improved electron injection in the light-emitting QD layer as evident from a decreased turn-on voltage and a reduction of emission originating from other layers than the QD layer of the LEDs.

Huang et al. (2008) fabricated a hybrid CdSe-ZnS QD (QD)-InGaN-GaN QW red LEDs. It was reported that the blue light from the InGaN QWs can be easily down converted to the red light using different blend ratios. The luminous flux and LE from the hybrid LED of 0.65 lm and 9.3 lmW^{-1} could be obtained keeping QD concentration as 40 $mg\,mL^{-1}$ of resin. It was revealed that from electroluminescence spectrum that the contribution of red light emission to the total light intensity was found to be 98%.

Cho et al. (2009) crosslinked colloidal quantum-dot layer. It can reduce charge injection barrier in a red light-emitting quantum-dot, LEDs by using a sol−gel TiO_2 layer for electron transport. It exhibited a high luminance (12,380 cd m^{-2}) and high power efficiency (2.41 lm W^{-1}). This technique may be incorporated in display device with a great promise for possible use in easy-to-fabricate, high-performance, illumination sources and large-area displays. A gold nanorod-enhanced light emission was reported by Yang et al. (2014a) in quantum-dot-doped polymer nanofibers. It was observed that there was a 67% increment in 600 nm red light emission efficiency on incorporating gold nanorods into quantum-dot-doped polymer nanofiber. The photostability was found to be increased by 100 min.

A highly efficient, ultrabright, low roll-off, inverted QD-based red light-emitting device (QLED) was reported by Dong et al. (2015). They used cesium carbonate films and solution-processed zinc oxide NPs as the hole blocking layers and electron injection, respectively. It was revealed that luminance of 165,000 Cdm^{-2} was obtained at a current density of 1000 $mAcm^{-2}$ for deep red device.

Fine tuning of emission color of Ce-doped yttrium aluminum garnet ($Y_3Al_5O_{12}:Ce^{3+}$, YAG:Ce) nanophosphor-based WLED was reported by Kim et al. (2016b). They coated CdSe/CdS/ZnS QDs onto the surface of the YAG:Ce NPs. It was observed that the luminescence spectra of the QD@YAG:Ce can be tuned by variation of QD to YAG:Ce weight ratios. Lin et al. (2016) reported highly efficient deep-red LEDs, which is based on type-II CdTe/CdSe core/shell QDs. CdTe/CdSe core/shell QDs synthesized through a green process have different PL emissions peaks at 642, 664 and 689 nm and it was observed these using three devices QDs with different PL peaks exhibited maximum external quantum efficiency of 5.24%, 5.74% and 6.19%, respectively.

Indium phosphide (InP) QDs have shown great potential as a replacement for CdSe QDs in display applications. However, the performance of InP-based QLEDs is still far behind that of the CdSe-based devices. The effects of different methods for improving the performance of InP-based QLED devices was investigated by Li et al. (2019a). They evaluated effect of magnesium doping in ZnO NPs used as an n-type electron transport layer, so as to balance charge transfer in InP-based QLED devices. It was found that ZnO band gap is broadened and its energy levels are shifted along with increase in resistivity by doping on increasing Mg content. It was revealed

that electron current density was reduced and device efficiency was improved. It was indicated that QD structures and devices in optimum conditions could prove be as current efficiencies of 11.6 cdA^{-1} to red InP QLEDs.

A highly efficient and stable red QLED was reported by Liu et al. (2020b). They used codoped lithium and magnesium along with magnesium oxide shell-coated zinc oxide nanoparticle layer (electron transport layer). It was observed that optimized QLED show a high peak EQE of (20.6%), long lifetime T_{95} of >11000 h, and low efficiency roll-off at high current.

10.2.4 Green light-emitting diodes

Steckel et al. (2006) synthesized $Cd_xZn_{1-x}Se$ alloy core nanocrystals. Then these were overcoated with $Cd_yZn_{1-y}S$ to create core−shell nanocrystals for use in QD-LED displays. It was found that these $Cd_xZn_{1-x}SeCd_yZn_{1-y}S$ core−shell nanocrystals can be used to fabricate color-saturated green−emitting QD-LEDs, which can be a potential for display applications.

Sun et al. (2007) reported green, orange, red, and yellow LEDs using CdSe core and ZnS or CdS/ZnS shell as emissive layers in the devices and it was observed that the maximum luminance was 3700, 3200, 9064, and 4470 cd m^{-2}, respectively. It was indicated that improved electroluminescent efficiency (1.1−2.8 cd A^{-1}), low turn-on voltages (3−4 V) and longer operation lifetimes of quantum-dot-based LEDs can be obtained by optimizing the thicknesses of the constituent layers of the devices. It was suggested that these QDs LEDs may be promising flat-panel displays applications.

The growth of InN, GaN, and InGaN QDs by molecular beam epitaxy (MBE) on either GaN or AlN templates was reported by Moustakas et al. (2008). InN QDs on GaN templates were found to occur without an InN wetting layer. The self-assembled GaN QDs were grown on AlN templates. It was observed that the self-assembly of InGaN QDs on GaN templates can find the applications in blue-green LEDs. It was indicated that InGaN/GaN multiple QDs (MQDs) were highly strained and at low injection, their emission is red shifted as compared to a single layer of QDs.

Park and Park (2011) fabricated LEDs with emission in the green range (540−610 nm). They grow self-assembled In-rich InGaN QDs on n-GaN via metal-organic chemical-vapor deposition. It was observed that emission wavelength of LED was red shifted from green (540 nm) to red (610 nm). This shift was attributed to an increase in the depth of potential wells of the InGaN QDs with increased roughness of the surface n-GaN layer.

Park et al. (2015) reported bright yellow−green-emitting $CuInS_2$ (CIS)-based QDs and two−band WLEDs using these QDs. They used metal−oleate precursors and 1-dodecanethiol for synthesis of yellow-green-emitting CIS QDs with CIS cores (QE = 31.7%). These CIS/ZnS/ZnS QDs exhibited a high QE (80.0%) and a peak at 559 nm, which is dominant wavelength of

blue LEDs. It was revealed that white light LEDs can be fabricated with coating of CIS/ZnS/ZnS on blue LEDs, which exhibited LE (80.3 $\mathrm{lm \cdot W^{-1}}$), CRI (73) and a high light conversion efficiency of 72.6%.

The InP/ZnS QDs were synthesized by Yang et al. (2015) via hot injection method. They used nontoxic $P(N(CH_3)_2)_3$ as precursor. It was found that triple-shell-coated InP/ZnS core−shell QDs of green, orange-red, and yellow colors could reach PL QYs as high as 0.50, 0.63, and 0.55; and FWHMs as narrow as 55, 71, and 76 nm, respectively.

Li et al. (2016) synthesized perovskite $CsPbBr_3$ QDs via hot-injection method as green phosphor for LEDs. It was reported that green light with an emission peak at 534 nm could be achieved using $CsPbBr_3$ QDs and GaN LEDs. The current-voltage characteristic of the green LED did not show any degradation as compared to GaN LEDs. It was also revealed that as-fabricated green LEDs exhibited a LE of 31.92 $\mathrm{lm\ W^{-1}}$.

Ko et al. (2017) synthesized highly efficient bright green-emitting Zn−Ag−In−S (ZAIS)/Zn−In−S (ZIS)/ZnS alloy core/inner-shell/shell QDs. They used a multistep hot injection method and zinc acetate dihydrate as precursor. It was reported that as-synthesized ZAIS/ZIS/ZnS QDs displayed a high PLQY (87%) with peak wavelength (501 nm). The green, red, and blue tripackage white DC−LEDs exhibited high LE of 72 $\mathrm{lm\ W^{-1}}$ and CRI of 95.

The heavy-metal-free InP/ZnS core/shell QDs with different fluorescence were prepared by Kuo et al. (2017) via green route. These InP/ZnS core/shell QDs exhibited maximum fluorescence at $\sim$ 530 nm and high fluorescence QY (60.1%). As-prepared multilayered InP/ZnS core/shell QD-LEDs showed highest luminance of 160 $\mathrm{cd\ m^{-2}}$ and external quantum efficiency (0.223%). It was predicted that these multilayered InP/ZnS core/shell QD-LEDs have a great potential in heavy-metal-free QD-LEDs for display applications in next generation.

The green QDs were prepared by Li et al. (2017). They used tris(mercaptomethyl)nonane (TMMN) as the capping ligand. It was observed that these TMMN-capped QDs exhibited QYs of $\sim$90% after ligand exchange with external quantum efficiency of 16.5%. The current efficiency and power efficiency of these were found to be 70.1 $\mathrm{cd\ A^{-1}}$ and 57.6 $\mathrm{l\,m\ W^{-1}}$, respectively. It was revealed that as-prepared devices exhibited high environmental stability.

It was reported by Kumar et al. (2018) that the structural and optical control of InP-based QDs can lead to high-performance LEDs. It was observed that zinc sulfide shells passivate the InP QD core and as a result, increase the QY in red and green-emitting QDs was observed by eight- and thirteen-fold, respectively. They fabricated WLEDs with LE up to 14.7 $\mathrm{lm\ W^{-1}}$ as well as color-rendering index up to 80.

QDs have high potential to fulfill the ever increasing demands for high-quality displays due to their outstanding size-tunable optical properties, high QY and reduced costs. The synthesis of efficient materials and their

integration in uniform and thin polymeric films are necessary for displays. Sadeghi et al. (2018) synthesized green− and red−emitting Cd-based QDs with QYs of 74% and 52%, respectively. These QDs were incorporated into the PDMS polymer matrix, which provide polymeric films with 123 × 68 mm for smart phone displays. It was suggested that these QD polymeric films show promising applications in smart phones.

In recent, the QY and stability of green QDs have been significantly improved. However, most of the progresses were achieved by using alloyed QDs, and the control of green emission QDs still remains challenging. Hao et al. (2019) reported synthesized thick-shell structure QDs (TSQDs) with saturated green-emission. They used tri-n-octylphosphine as both ligand as well as solvent to extract the redundant ions from the QDs surface. It was observed that as-prepared TSQDs exhibited high QY reaching up to 75% and tunable precise emission properties (532 nm).

The CdSe/ZnS core−shell QDs were synthesized by Ramalingam et al. (2019) via a chemical route. They used bioconjugated organic amino acid (L-Cysteine). The diameter of as-prepared QDs was found to be 3 nm with uniform size distribution. The optical properties QDs exhibited an absorption and emission peak at 515 and 525 nm respectively, at room temperature. It was indicated that these QDs exhibited emission in the spectral range at 516−535 nm, which is particularly find application in green LEDs.

The synthesis of heavy metal (or Cd) free QD-LEDs have been reported by Ippen et al. (2019) for all three colors. They developed heavy metal free QDs with high QY (> 95% for red and green and >80% for blue). A high efficiency was observed for these heavy metal free QD-LEDs with EQE = 16.9, 13, and 9% for red, green, and blue, respectively. The impact of shell thickness on efficiency performance of device was also evaluated.

Yang et al. (2020) reported QD films based on a poly(zinc methacrylate) coating. These alloyed CdZnSeS/ZnS QDs (QDs@PZnMA) are green−emitting with high refractive-index $BaTiO_3$ NPs. A 7.5−, 11.3−, 8.5−, and 8.6− fold increase in the absorption coefficient, scattering coefficient, optical density and green light emission QD films was observed as compared to films having identical mass percentage of pristine QDs. It was proposed that it has a potential for developing QD optical films with enhanced light emission and high scattering for flexible displays.

Zheng et al. (2020) prepared green carbon QDs (g-CQDs) with high fluorescent QY and high product yield via solvothermal method using 2,7-dihydroxynaphthalene and ethylenediamine as the carbon source and nitrogen dopant, respectively. It was revealed that the maximum product yield (70.90%) and QY (62.98%) values of g-CQDs could be achieved. They prepared WLEDs by combining these g-CQDs and blue chip.

μLEDss are considered as ideal source of light for next generation and high-speed visible light communication InGaN QDs have been proposed as the active region of (Wang et al., 2021a, b). Green InGaN QDs have an

external quantum efficiency of 18.2%, which is almost two−folds than present green μLEDss. It was indicated that InGaN QDs can provide a solution to μLEDss for display and visible light communication applications, as these are fully compatible with current LEDs industrial technology.

10.2.5 Orange light-emitting diodes

Kim et al. (2008) synthesized Mn-doped $Zn_{1-x}Cd_xS$ QDs via reverse micelle approach. It was found that band gap energy of $Zn_{1-x}Cd_xS$:Mn QDs can be tuned to a higher energy by increasing the Zn content. The average size of these QDs was calculated as 3.6 nm. A high QYs (14%−30%) was exhibited depending on the composition of the core QDs. Orange and WLEDs were fabricated using these CdS:Mn/ZnS QDs.

Nizamoglu and Demir (2009) reported Förster resonance energy transfer-enhanced color-conversion. They used colloidal semiconductor QD nanocrystals to make reddish-orange LEDs, which can find applications in ultraefficient SSL. Energy gradient hybrid structure from cyan- and orange-emitting CdSe/ZnS NCs (492 and 588 nm, respectively) can be obtained. A relative increase in quantum efficiency of 15.1% in reddish-orange full color-conversion was observed for the integrated hybrid cyan-orange NC layer.

Song and Yang (2012) reported core/shell structured QDs (CIS/ZnS) exhibited tunable emissions of yellow-orange with excellent QYs (55%−91%). A white QD-LED was fabricated using by CIS (2 h)/ZnS QD as a blue-to-yellow color converter. They also fabricated white QD-LED by blending of yellow and O-QDs so as to improve a color rendering property.

Shen et al. (2013) used solution-processed ZnO NPs as the electron injection/transport layer, bilayer structure of poly[9,9-dioctylfluorene-*co*-*N*-[4-(3-methylpropyl)]-diphenylamine] (TFB)/poly(ethylenedioxythiophene): polystyrene sulfonate (PEDOT:PSS) as the hole transport/injection layer and CdSe/CdS/ZnS core−shell QDs as the emitting layer. It was observed that highly bright orange-red and green QD-LEDs could be obtained with peak luminances and power efficiencies as $\sim 30\,000$ & $\sim 52\,000$ cd m^{-2}, and 16 & 19.7 lm W^{-1}, respectively. It was proposed that these can be commercialized for use in QD-based displays and SSLs.

Aniline GQDs (Chemically derived) were used as lumophores and LEDs exhibiting orange, green, and red electroluminescence with high color purity were fabricated by Kwon et al. (2016). They evaluated external quantum efficiency and maximum current efficiency of 1.28% and 3.47 cd A^{-1}, respectively.

The synthesis of Mn-doped cesium lead halide ($CsPbX_3$) PQDs has been reported by Zhu et al. (2017). It was observed that optical properties of as-prepared nanocrystals remained same even after several months. They fabricated red-orange LEDs by coating the composite onto ultraviolet LED chips.

This present approach may open new avenue for doping other ions in $CsPbX_3$ QDs at room temperature and developed capability in as − prepared essential material for applications in memristors and other devices.

Ren et al. (2020) proposed a facile posttreatment doping method enabling preparation of highly luminescent low-toxic $CsPbX_3$:Mn^{2+} PQDs from nonluminescent Cs_4PbX_6 PeQDs. It was reported that monodispersed $CsPbX_3$:Mn^{2+} PeQDs exhibited excellent photophysical properties such as PL QY (87%). It was revealed that variation of halide composition in Cs_4PbX_6 PeQDs or Mn doping concentration, they were able to prepare a series of $CsPbX_3$:Mn^{2+} PeQDs, which can have tunable emission. They fabricated $CsPbX_3$:Mn^{2+} Q-LED, which exhibited excellent orange light with LE of 24 lm W^{-1}.

10.2.6 Yellow light-emitting diodes

Lv et al. (2012) used InGaN/GaN multilayer QD in active regions for yellow-green LEDs. It was observed that on increasing growth temperature and switching the carrier gas (from N_2 to H_2), using improved growth parameters, a 10-layer InGaN/GaN QD LED was obtained. It was revealed that electroluminescence peak wavelength also shifted from 574 to 537 nm.

Denault et al. (2013) fabricated devices using CdSe/ZnS core/shell QDs (red-emitting) with $Y_3Al_5O_{12}$:Ce^{3+} (yellow-emitting) or $Lu_3Al_5O_{12}$:Ce^{3+} (green-emitting) and InGaN LED (blue-emitting). It was reported that devices with $Y_3Al_5O_{12}$:Ce^{3+} with QDs (590 nm) could achieve LE (57 lm W^{-1}) and CRI (81), while devices with $Lu_3Al_5O_{12}$:Ce^{3+} with QDs could achieve CRI (90) and LE (22 lm W^{-1}).

He et al. (2018) studied inorganic perovskite $CsPb(Br_xI_{1-x})_3$ QDs with QY of 50% as yellow light convertor for LEDs. It was reported that highly pure yellow LEDs were obtained, when x was kept 0.55. It gave LE (13.51 l m W^{-1}) with an emission peak at ∼570 nm. It was concluded that $CsPb(Br_xI_1 - _x)_3$ QDs are potential candidate for yellow LEDs with high purity.

Gu et al. (2021) used hydrothermal method for the preparation of nitrogen doped GQDs (N-GQDs). They used citric acid and o-phenylenediamine as precursors. It was reported that as-produced N-GQDs exhibited blue color with a QY (58%) in presence of 365 nm UV light illumination. As the concentration of N-GQDs increases, the PL exhibits an obvious red-shift from blue to yellow. A high PL QY of 28% could be with yellow luminescence is achieved under 405 nm excitation, using N-GQDs in solid state. A WLEDs device was constructed by adjusting thickness and concentration of N-GQDs in blue emitting InGaN chips.

10.2.7 Other light-emitting diodes

Qian et al. (2011) developed devices consisting of a quantum-dot emissive layer, which was sandwiched between an electron transport layer of ZnO

NPs and an organic HTL. It was reported that as-fabricated devices exhibited maximum luminance and power efficiency values of 4,200 cd m^{-2} & 0.17 lm W^{-1}, 68,000 cd m^{-2} & 8.2 lm $W^{-1}$and 31,000 cd m^{-2} and 3.8 lm W^{-1} for blue, green, and orange−red emission, respectively. It was also revealed that with the incorporation of the ZnO NPs, these devices have high environmental stability with operating lifetimes more than 250 h in low vacuum.

Jun et al. (2013) prepared a highly luminescent and photostable QD−silica monolith substance via base-catalyzed sol−gel condensation of silica. They heavily doped SM with 6-mercaptohexanol exchanged QDs up to 26 wt.% (12 vol.%) without any particle aggregation. These green and red light-emitting QD−SMs were then applied as color-converting layers on blue LEDs. It was observed that external quantum efficiency could reach up to 89% and 63% for the red and green QD−SM, respectively. A WLED made with a mixture of these green and R-QDs in the SM exhibited an efficacy of 47 lmW^{-1}.

Highly efficient tandem quantum-dot LEDs were proposed by Zhang et al. (2018b). They used an interconnecting layer (ICL) with the structure of ZnMgO/Al/HATCN/MoO_3. It was reported that as-prepared ICL exhibited efficient charge generation/injection capability, high transparency, and high robustness. The tandem QLEDs [full color (red (R)/green (G)/blue (B)] show high current efficiency and external quantum efficiency: 41.5 cdA^{-1} and 23.1%, 17.9 cdA^{-1} and 21.4%, 121.5 cdA^{-1} and 27.6% for R-QLEDs, B-QLEDs, and G-QLEDs, respectively. The EQEs of R-, G-, and B-QLEDs were more than 21%. The R-, G-, and B-QLEDs can still sustain their external quantum efficiency at 96%, 99%, and 78%, respectively. It was suggested that these full-color tandem QLEDs have long operational lifetime, high efficiency, high color purity, and low roll-off efficiency, and hence can prove to be ideal candidate for the SSL and full-color displays.

10.3 Night vision

Taking into account the requirements of different practical usages at night, LEDs are applied for infrared lighting in night vision operations comprising security cameras. It has been shown that a ring of LEDs around a video camera is a low-cost and successful kit for chroma keying in video production applications (Cabrera, 2019). Night Vision Imaging Systems (NVIS) are used in military domains such as electronic combat reconnaissance aircraft (Sabatini et al., 2016; Chen et al., 2017a).

Wu et al. (2012) examined the feasibility of using QD phosphor-based LEDs in aviation uses that solicit NVIS conformity, recommending that white QD phosphor-based LEDs can be tailored to show greater suitability with NVIS than commercial LEDs. It was expected that the QD

phosphor-based LEDs reach important goals in cockpit illumination and LED indicator lights of aviation panels.

Chen et al. (2017a) stated that LED night vision imaging detection has been applied in numerous areas. The usage of LED array as a light source possesses the advantages of reduced price and small dimension. It was revealed that utilizing the degradation model, the target image was recovered with the help of the model-based image processing algorithms and that the experimental results confirmed the efficacy of this method.

An interesting review by Zheng and Zhu (2020) emphasizes three classes of emerging near-infrared (NIR) emitting materials used in LEDs. They reported the advantages and disadvantages of these three types of materials (organic materials, inorganic QD materials, and organic−inorganic hybrid perovskite materials) used to fabricate the appropriate devices (OLEDss, QD LEDs, and perovskite LEDs), showing that NIR QLEDs possess the potential for military uses, such as night vision-readable display and iris identification systems.

Vasilopoulou et al. (2021) reported NIR LEDs based on solution-processed semiconductors, such as halide perovskites and colloidal QDs, which are suitable technological stages for night vision, surveillance, and optical communications. This research listed new developments on emissive materials synthetic methods and essential qualities that increase the performance of manufactured light-emitting devices.

10.4 Data communication

In the data communication structure, there is a requirement for higher data rates with great reliability and secure means of accessibility (Kate and Husain, 2017). The use of LEDs increases efficiency in terms of data fidelity, data rate and cost; thus permitting the progress of light fidelity (Li-Fi) technology and the Visible Light Communication (VLC) system (Kate and Husain, 2017; Yu et al., 2021). The unique properties of QDs determine their notable application in optical technologies, such as QD-LEDs that can be used as an optical transmitter in VLC (Xiao et al., 2016; Yulin et al., 2017; Choi et al., 2018; Pradhan et al., 2019; Vahabzad et al., 2019).

A new procedure has been described by Ruan et al. (2016) for the manufacture of a type of QD-WLEDs from green- and red-emitting $AgInS_2$/ZnS core/shell QDs coated on GaN LEDs. It has been mentioned that the modulation bandwidth of QD-WLEDs was much enhanced in comparison to that of YAG:Ce phosphor-based WLEDs, showing that $AgInS_2$/ZnS core/shell QDs have the potential to improve the bandwidth in VLC. The use of colloidal semiconductor QDs for light conversion of InGaN sources in VLC applications was analyzed by Leitao et al. (2017). They presented a colloidal QD/polymer composite format of color converters and reported some samples of such color converting composite that were hybridized with a μLED to create

hybrid sources for a demonstration of free-space VLC over 10 cm with data rates up to 1 Gb s^{-1}.

A microwave-assisted heating technique to manufacture multicolor QD-based phosphors in 30 s was investigated by Zhou et al. (2018) using a combination of QDs and sodium silicate aqueous solution. They indicated an application of the QD-based phosphors in VLC, noting that the bandwidth modulation reaches 42 MHz. Cao et al. (2019) developed a high bandwidth GaN-based WLED that was obtained using blue LED chip (GHz bandwidth) with a combination of CdSe/ZnS QDs. It provides an advantageous solution for the creation of high bandwidth WLEDs for VLC uses in free space. Li et al. (2019b) exhibited an interesting portable VLC system, which is suitable for indoor short-distance communication technology using CdSe/ZnS QDs as a light converter, creating a portable transmitter and receiver based on digital signal processors and observing that under a direct bias voltage of 2.70 V, the highest transmission rate is 267 Kbs^{-1}.

Recently, Singh et al. (2020) reviewed the latest advances for VLC applications based on LEDs but principally on semipolar μ-LEDs and μ-LED-based arrays with high bandwidths. It has been highlighted that a significant application of great interest for marine exploration and underwater connectivity is the use of VLC for underwater optical wireless communication, recalling the reported case of a data rate of 2 Gbps over a 3 m air-underwater channel using a single layer QD blue μ-LED (Singh et al., 2020. Wei et al., 2020a).

Li-Fi, which represents a wireless technology that is not only environment-friendly, but also low cost for the future of communication (Meshram and Meshram, 2020), demands wearable and full duplex configuration because of its important role in applications such as smart wearables and "Internet of Things" (Shan et al., 2020). They described a perovskite QD-based light-emitting/detecting bifunctional fiber built with the help of a hybrid strategy and showed that the creation of this type of fiber is promising for the manufacture of future smart wearables.

Wan et al. (2021) proposed a new plasmonic WLED using the combination of a nanohole LED (H-LED) with QDs and silver NPs (Ag NPs) together (M-LED), explaining that the improved M-LED exhibited a maximum CRI of 91.2 and a data rate of 2.21 Gbs^{-1} at a low current density of 96 Acm^{-2} (60 mA). Here, a promising scope for WLEDs in lighting and VLC applications has been discussed.

10.5 Agriculture and horticulture

In recent years, a lot of research has been carried out in the fields of horticulture and agriculture, due to the diverse successful characteristics; LED lighting systems are considered a new profitable technology for plant growth and a promising tool to improve crop production (Mitchell et al., 2012; D'Souza

et al., 2015; Hasan et al., 2017; Viršilė et al., 2017). Many studies have revealed that the monochromatic character of LEDs can help diminish the incidence of pest and diseases pressure in growing plants and that some valuable features such as energy efficiency, long lifetime, and flexibility have indicated that LEDs are more adequate for future agricultural lighting methods than conventional lighting methods (Darko et al., 2014; Gomez and Izzo, 2018; Al Murad et al., 2021; Koushik et al., 2021).

The feature, related to the fact that QD can emit specific wavelengths of light, when supplied with energy, has been exploited to shift incoming light into a certain part of spectrum that plants can most effortlessly utilize for photosynthesis (Mission, 2021). QDs technology has demonstrated some excellent benefits for the lighting sector, including the application area related to horticulture.

A new procedure has been developed by Song (2016) for the manufacture of a LED utilizing QDs as phosphor. He constructed the multiwavelength LED device to show the possibility of its application for the plant factory. It was indicated that the good use of QD can be made with the multifunction LED light source.

Zhang et al. (2019) have fabricated some exceptional WLEDs and LEDs for plant growth with the help of red-emitting $CsPb_{1-x}Ti_xI_3$QDs@glasses, showing that a series of Ti-doped $CsPbI_3$ QDs were prepared in borosilicate glass ($SiO_2-B_2O_3$-ZnO) and that the WLED was built with the help of red-emitting $CsPb_{1-x}Ti_xI_3$QDs@glasses and yellow-emitting Ce^{3+}:YAG phosphor under excitation of InGaN blue chip.

Chung et al. (2020) reported that four kinds of QD lamps (QDLs) that emit different wavelengths of light were positioned in the perilla greenhouse in Milayang (Korea) revealing that QDLs considerably increased in the perilla leaf growth in comparison with control LED lamps and that perilla leaves exposed by Q2R lamps considerably improved the contents of biologically functional constituents (chlorophyll, total flavonoid, and phenolic-acid compounds).

Choi et al. (2019) have studied the consequences of LED and QD-LED irradiation on seed germination and microbial growth, in the time of the red radish (*Raphanus sativus* L.) sprouts cultivation. It was reported that the red hypocotyl was exceptional in blue light and QD-LED light. It was revealed that when red radish seeds were germinated in the dark and cultivated for a period of 7 days as sprouts and then irradiated with QD-LED light for 24 h, the seeds furnished some superior quality red radish sprout showing a diminished level of *E. coli* contamination.

Liu et al. (2021a) investigated the luminescent spectrum of LEDs based on QD materials, which was projected depending on the photosynthetic action spectrum (PAS) of plants. For the case of the three-band QD-based LEDs (QLEDs), it was found that photosynthetic action factor (PAF) has the maximal value of 8.088 and the induced photosynthetic index (IPI) has the

maximal value of 4.012. In the case of the four-band QLEDs, the maximal value of 7.689 was calculated for PAF and the maximal value of 3.818 was determined for IPI. They showed that in the issue related to the vision features, the four-band device exhibited a maximal value of 93 for CRI and a maximal value of 2053K for the correlated color temperature (CCT). They observed that the obtained results had consistence with the simulation ones, certifying the feasibility of manufacturing growing lamps with QD materials.

Jung et al. (2021) demonstrated that the quantity of Rg1 and Rg3, the most abundant ginsenosides, which are found in ginseng sprout, increased remarkably in the root of ginseng sprouts under the QD-LED method in comparison with the LED method, indicating that the cultivation of ginseng seeds using QD-LED method can determine the progress of high-productivity products.

10.6 Antimicrobial technology

LEDs have been used to obtain air disinfection, water disinfection and purification, surface decontamination, and food preservation (Koutchma and Orlowska, 2012; Kim and Kang, 2018; Ogonowska et al., 2019; Prasad et al., 2020; Singh et al., 2021b; Kim and Kang, 2021). Ultraviolet (particularly UVC) irradiation has especially attracted tremendous attention as one of the most successful antiviral procedures (Bhardwaj et al., 2021; Memarzadeh, 2021). The UV-LEDs have shown the potential for an extensive domain of applications in sterilization, sensing, and detection (Muramoto et al., 2014; Chen et al., 2017b; Won et al., 2018; Memarzadeh, 2021).

Yang et al. (2014b) showed that high internal efficiency and high temperature stability of UV LEDs at 308 nm were obtained utilizing high density GaN/AlN QDs grown with the help of metal organic vapor phase epitaxy (MOVPE). It was observed that the value of the internal quantum efficiency was 62%.

Chen et al. (2016) communicated the enhanced excitation and directional fluorescence emission (DFE) of QD by Ag NPs using theoretical calculations, emphasizing that enhanced DFE is important for biological and medical detection processes. It has been established that a monolayer Ag NPs showed a dominant enhancement in DFE for monolayer or low concentration QDs in LED, highlighting the significance for the design and progress of high-efficiency QD LEDs.

A new solid-state-based broadband UV light source was developed by Cho et al. (2020), which could substitute arc-lamp-based uses. Taking into account that group III-nitride UV LEDs did not exhibit a broad UV spectrum region, which limits their use in areas such as medical therapy and UV spectrophotometry, they obtained different emission wavelengths in the UV

region from the GaN QDs grown on the truncated pyramid structures, which furnish a high-efficiency broadband UV spectrum.

Elgammal (2020) reported that silicon QD-based LEDs produced with the help of cyclohexasilane can affect a number of industries but in response to the COVID-19 crisis, their efficiency recommends them for public areas, where infected droplets constitute important risks for public health.

Deep ultraviolet (DUV) LEDs furnish some important benefits such as compact size, low consumption, and long lifetimes. Brault et al. (2021) presented that $Al_xGa_{1-x}N$ LEDs emitting in the UVB (230−320 nm) and UVC (below 280 nm) regions are of significant technological interest for the medical and environmental applications as alternatives to mercury-based lamps. Noticing that some improvements of their characteristics are needed, they examined the potential of $Al_yGa_{1-y}N$ QDs as DUV emitters.

10.7 Recent developments

QDs are useful in LEDs for displays, memristors, smartphones, etc. These fabricated LEDs can exhibit a variety of colors, apart from WLEDs such as blue, red, green, orange, etc. These LEDs can also find applications in data communication, night vision, agriculture, horticulture, etc. Some recent developments of QDs-based LEDs are summarized in Table 10.1.

TABLE 10.1 Recent advancement on LED application of quantum dots.

Material used	Application	References

Graphene quantum dots	Visible light-activated antibacterial activity	Huang et al. (2021a, b)
Carbon dots	Antimicrobial photodynamic	Romero et al. (2021)
ZnO QDs	Antimicrobial	Gangadoo et al. (2021)
Carbon QDs	Antimicrobial	Ayad et al. (2021)
Nitrogen–doped graphene QDs	Antimicrobial therapy	Kuo et al. (2021)

10.8 Conclusion

LEDs are presented as an attractive option to standard light sources, being considered today's perfect lighting technology due to their high energy efficiency, low cost, and longer lifetime. QDs have produced considerable interest due to their unique properties, and are being presented as one of the promising candidates for application in LEDs. The recent trends in QDs applications for LEDs have been reviewed, including those related to the following areas of utilization: displays, lighting, data communication, agriculture, horticulture, and antimicrobial technology. There is great potential for QDs as a unique material solution that can allow the successful achievement of a broad range of applications in the field of LEDs.

Chapter 11

Application of quantum dots in biomedical and biotechnological fields

Anca Armăşelu[1] **and Priyanka Jhalora**[2]

11.1 Introduction

Owing to their unique size-dependent features, fluorescent nanoparticles (NPs) or quantum dots (QDs) have attracted the attention of scientists all over the globe in the last few decades. There is an increasing concern in developing environment-friendly procedures to synthesize these NPs because they enhance biocompatibility and avoid the production of toxic by-products (Plaza et al., 2016).

Due to the advent of nanobiotechnology, some modern biological synthesis works of nanomaterials (NMs) have succeeded in implementing "Green chemistry" strategies, which are globally sustainable and economically viable (Abdel-Salam et al., 2020). The green revolution and scientific developments in the realm of biological sciences, agricultural biotechnology, food technology, and nanotechnology follow the route of a novel scientific perceptiveness (Palit, 2020).

Some substantial studies have explained the conception or synthesis of materials with nanoscale accuracy (Ameta and Ameta, 2016a,b) using material science, which is nanotechnology (Pandey et al., 2015; Ameta and Ameta, 2016c). These studies have described the diverse aspects of synthesis of NPs, characterization, and their crucial applications, focusing on the biogenic synthesis of NPs and their use (Ingale and Chaudhari, 2013; Bhatt et al., 2020a).

QDs have been presented as the central notion of nanoscience and nanotechnology since their inception and remain an active and intense domain of exploration in applied nanomaterial research (Damian et al., 2011; Ameta et al., 2014;

Quantum Dots. DOI: https://doi.org/10.1016/B978-0-12-824153-0.00011-2
© 2023 Elsevier Inc. All rights reserved.

Benjamin et al., 2014; Solanki et al., 2018; Ameta et al., 2019a,b; Armăşelu, 2019; Liu et al., 2020a; Ameta et al., 2020). QDs possess numerous distinctive constitutional, physicochemical, and photochemical characteristics that make them encouraging candidates in the areas of solar cells, laser, memory, light-emitting diodes (LEDs) (Armăşelu, 2017), photovoltaics, photodetectors, photocatalysts (Ameta et al., 2019c; Bhatt et al., 2019a), quantum computers (Ameta et al., 2019c), wastewater treatment (Bhatt et al., 2019b,c; Jat et al., 2019), and bioimaging applications (Ardelean et al., 2011; Armăşelu et al., 2011a,b; Damian et al., 2010).

The QDs show unique optical properties, which depend on their size, shape, and surface chemistry, and in spite of the fact that research on QDs is at a relatively early phase, their high biocompatibility and reduced cytotoxicity have already been established in vitro and in vivo, increasing the interest in this type of NM as compared to others (Perini et al., 2020).

QDs and their composites are modern and notable structures, which present unique and significant properties. Here, the basic properties of QDs, some key aspects related to the synthesis techniques of QDs, and the latest advances in the field of QDs applications in sensing, bioimaging, biolabeling, and targeted drug delivery have been presented. This work also provides some toxicological characteristics of QDs and their composites.

11.2 Biolabeling and bioimaging

Biolabeling is nothing but tracking individual cells using any material. QDs have been used for labeling of cells. It is all due to the florescence of QDs. This can pass to daughter cells upon cell division with florescence labels in such cases. These have also being used before surgery by labeling lymph nodes with florescence. Bioimaging refers to any imaging technique in the field of biomedical and biotechnology. Here, bioluminescence is used in the diagnosis of some diseases. One can visualize different infections, localizing cancer growth by creating bioimages of different internal organs and their functions.

Wolcott et al. (2006) reported a simple aqueous synthesis of silica-capped, highly fluorescent CdTe QDs. These CdTe QDs are quite useful as the emission can be tuned to the near-infrared, where tissue absorption is at the minimum. Leakage of toxic Cd^{2+} can be prevented by a silica shell. These silica shells help in increasing photostability in tris-borate-ethylenediaminetetraacetate and phosphate-buffered saline buffers. They used poly(ethylene glycol) and thiol-terminated biolinkers to functionalize silica-capped QDs to improve their biocompatibility. Conjugation specificity and bioactivity of as-synthesized thiolated QDs was confirmed by streptavidin − maleimide and biotinylated polystyrene microbeads. It was reported that these functionalized, silica-capped QDs are ideal labels, safe, robust, easily synthesized, and readily conjugated to biomolecules. They find a number of applications in biolabeling and imaging.

Li et al. (2007) synthesized aqueous CdS QDs in a direct and environment-friendly manner at room temperature. They reported the feasibility of aqueous CdS QDs as an imaging tool with *Salmonella typhimurium* cells, when 3-mercaptopropionic acid (MPA) was used as the capping molecule. The QDs exhibited stronger emission at higher pH and MPA/Cd ratio of 2. It was claimed that aqueous CdS QDs displayed a lifetime of 12 h under UV light with an excellent stability. An ease of processing and good PL properties of these aqueous CdS QDs provided a low-cost and practical approach for single-target imaging application.

Erogbogbo et al. (2008) prepared highly stable aqueous suspensions of Si QDs. It was found that the optical properties of Si nanocrystals are retained. These micelle-encapsulated Si QDs can be used for detecting pancreatic cancer cells. These silicon QDs may prove to be a significant optical probe in biomedical diagnostics.

Biologically compatible and water-soluble CdSe QDs were synthesized in aqueous medium by Liu et al. (2009) using L-cysteine as the capping agent. It was revealed that molar ratio of Se/Cd and the reaction time are deciding factors for the size distribution of CdSe/L-cysteine QDs. The fluorescence intensity of bovine serum albumin (BSA) was largely quenched with the addition of QDs, but it slightly enhanced initially and then quenched on addition of BSA to solution of QDs. They suggested that CdSe/L-cysteine QDs can be used as a probe for labeling bacterial cells and biological molecules.

Allen et al. (2010) reported the synthesis of InAs QDs with a ZnCdS shell. These can be used for biological imaging as they show stable and bright emission in the near-infrared (NIR, 700−900 nm) region. They opined that these NIR QDs can image tumor vasculature in vivo at deeper penetration depths with higher contrast than visible emitting CdSe(CdS) QDs. Tan et al. (2013) prepared nanoscaled light-triggered nitric oxide (NO) delivery consisting of chitosan (CS)-based *S*-nitrosothiols (SNO) and encapsulated silver sulfide QDs (Ag_2S QDs) and used for vehicles NIR fluorescence imaging. They used ethylenediaminetetraacetic acid (EDTA) to conjugate water-soluble Ag_2S QDs with the CS-SNO. They performed cell imaging. It was demonstrated that Ag_2S-CS-SNO nanospheres could emit observable NIR fluorescence and also release NO in living cells.

Uniform molybdenum disulfide (MoS_2)/tungsten disulfide (WS_2) QDs were prepared by Xu et al. (2015) via a combination of sonication and solvothermal treatment at a mild temperature. It was reported that as-prepared QDs have monolayer thickness (average size of about 3 nm). A good cell permeability, strong fluorescence, and low cytotoxicity make these QDs quite promising and biocompatible probes for in vitro imaging.

Justin et al. (2016) synthesized reduced graphene oxide (GO)−iron oxide QDs with photoluminescent and superparamagnetic properties. They used a green, hydrothermal method that reduced and shattered graphene nanosheets simultaneously to form QDs. A drug could be loaded onto the surface of

these QDs, with a loading ratio of drug to QD as 0.31:1. These have a potential to be used in cancer photothermal therapy. A suspension of QDs ($100\ \mu g\ mL^{-1}$) can be used for photothermal ablation of HeLa cells in vitro in presence of near infrared irradiation.

Nitrogen and phosphorus functionalized Ti_3C_2 MXene-based QDs (N,P-MQDs) were prepared via a top−bottom hydrothermal method by Guan et al. (2019). It exhibited pH resistance capacities and excellent photostability. These N,P-MQDs are highly sensitive toward Cu^{2+} ions and may be used for label-free fluorescence platform for Cu^{2+} detection. This is a low cost, sensitive, and environment-friendly method.

Xue et al. (2019) synthesized lignin hybridized CQDs (L-CQDs) via hydrothermal route. They used different molar ratios of ethanediamine and citric acid. As-obtained L-CQDs with almost spherical morphology were found to be <10 nm (diameter). It was reported that L-CQDs exhibited excitation-dependent photoluminescence (PL) behavior and maximum emission of L-CQDs exhibited a red-shift (longer wavelength) with a decrease in intensity on increasing excitation wavelengths. As-prepared L-CQDs have low good cellular biocompatibility and cytotoxicity indicating that there is a potential of these L-CQDs for bioimaging applications.

Qu et al. (2020) reported synthesis of bifunctional ibuprofen-based carbon QDs (ICQDs) via a simple one-step microwave-assisted method. As-prepared ICQDs exhibited low toxicity, high stability, good biocompatibility, and negligible cytotoxicity in water. It was reported that as-produced ICQDs had a decent imaging ability and excellent antiinflammatory effects in vivo, simultaneously. Shahid et al. (2020) reported hydrothermal synthesis of biocompatible, polyethyleneimine (PEI) surface passivated carbon dots (CDP) using mint leaves as a green source. The biolabeling potentials of nonpassivated C-dots and CDP was evaluated in the breast cancer (MCF-7) cells, when cytotoxicity was found to be concentration dependent. It was reported that C-dots synthesized from a herbal source (mint) can be used for different biolabeling applications as well as antioxidant activity.

11.3 Targeted drug delivery

Nanotechnology has the potential to develop quantitative and sensitive methods to diagnose and detect cancer. Semiconductor QDs are NPs that have intense and stable fluorescence, and these could help in the detection of various cancer biomarkers in blood assays, cancer tissue biopsies, and also as contrast agents for medical imaging. QDs are promising materials to expand to in vitro analysis, which can be extended to cellular, tissue, and whole-body multiplexed cancer biomarker imaging.

Detecting cancer at an early stage is a current challenge in the treatment of cancer. This will be supported by targeted drug delivery in and around tumors at concentrations, which decreases the growth rate of the tumors and

continues to be the primary challenge in the treatment of cancer. In most of the cases, the malignancy of tumors is only detected when it has reached an advanced stage and then chemotherapeutic drugs will be increasingly toxic to healthy cells. A targeting drug delivery system has a moiety that can recognize a tumor with a drug-loaded vesicle. Detection systems of malignant tumors involve tissue biopsy and magnetic resonance imaging (MRI), where a single system is needed that is capable of targeting drug delivery as well as imaging the delivery process, simultaneously. Here, the integration of biomaterials and semiconductor QDs can be useful for addressing these problems of cancer therapy.

Misra (2008) used biodegradable chitosan (*N*-acetyglucosamine) for targeted drug delivery to tumors and QDs noninvasive imaging. It was reported that drug-loaded chitosan-encapsulated ZnO:Mn^{2+} QDs provided a potential platform for drug delivery to targeted tumors and this delivery process was documented, simultaneously. Core−shell structured multifunctional nanocarriers (NCs) of ZnO QDs-conjugated gold NPs (Au NPs) were synthesized by Chen et al. (2013). It was indicated that camptothecin (CPT) release from these NCs was much higher at pH 7.4 than 5.3. It was reported that both NCs; and CPT-loaded NCs provided high anticancer activity against Hela cells.

Wang et al. (2013a) prepared GQDs with strongly green-PL, which were surface-passivated by polyethylene glycol (GQDs-PEG). It was observed that the PL quantum yield of as-prepared GQDs-PEG was around 18.8% with 400 nm excitation. They reported that surface-passivated PEG on GQDs can load the drug by hydrogen bonding apart from enhancing PL intensity. The GQDs-PEG have high specific surface area, which provide these higher loading capabilities (2.5 mg mg^{-1}) to carry the drug. As-fabricated GQDs-PEG were suitable for cell imaging and as drug carrier.

A novel QDs-based multifunctional nanovehicle (DOX-QD-PEG-FA) was designed for targeted drug delivery, fluorescent imaging, tracking, and cancer therapy, in which the GSH−CdTe QDs play a key role in imaging and drug delivery. The antineoplastic drug doxorubicin hydrochloride (DOX) was loaded on the GSH−CdTe QDs by Chen et al. (2014) via a condensation reaction. A PEG shell was introduced to wrap these DOX-QDs. The NPs were then decorated with folic acid (FA) to actively target particularly cancer cells and prevent the nanovehicles from being used up by normal cells allowing them to target HeLa cells that express the FA receptor. In vitro studies revealed that this multifunctional nanovehicle can deliver DOX specifically to the targeted cancer cells, and on reaching the tumor cells the FA on the DOX-QD-PEG surface increased the drug concentration so as to achieve higher curative effect. It was reported that this multifunctional DOX-QD-PEG-FA system exhibited great promise for tumor imaging, targeting, and therapy.

Wu et al. (2014) prepared dual-functional NMs consisting of QDs and an anticancer drug methotrexate (MTX). Hydrophilic $AgInS_2$/ZnS QDs were

obtained by ultrasonication by introducing the amphiphilic polymer, poly (maleic anhydride-alt-1-octadecene) (PMAO). Then MTX was covalently coupled to the surface of the $AgInS_2$/ZnS QDs by carbodiimide chemistry. It was indicated that these hydrophilic PMAO-coated $AgInS_2$/ZnS QDs exhibited negligible cytotoxicity, but $AgInS_2$/ZnS QDs conjugated with MTX were taken up effectively by human cervical (HeLa) cancer cells. It was suggested that $AgInS_2$/ZnS QDs conjugated with MTX may be a promising candidate for cancer therapeutics and diagnosis in future.

Samantara et al. (2016) developed a method to synthesize carbon QDs from Good's buffer. As-synthesized CQDs emitted a bright greenish blue colored fluorescence on exposure to UV irradiation (365 nm). This bright fluorescence of CQDs makes them useful probes for cellular imaging. More than 95% survival rate was found when H357 (human oral squamous carcinoma) and HEK293 (human embryonic kidney) cells were treated with these CQDs. The low cytotoxicity of Good's buffer-derived CQDs opens the door to biomedical applications. They easily loaded an anticancer drug DOX on as-prepared CQDs. They also explored delivery efficiency to the target cells via in vitro treatment of cancerous cells. CQDs-supported DOX exhibited a higher killing rate as compared to only DOX, which may be due to easy internalization and effective pH-triggered release inside the cells.

Rai et al. (2017) used lignosulfonate lignin as a carbon source for the synthesis of water-soluble reduced fluorescent carbon dots (r-FCDs). Then these r-FCDs were employed for bioimaging applications and as a curcumin nanocarrier. As-prepared r-FCDs were obtained under microwave irradiation after reduction with $NaBH_4$. The average diameter of r-FCDs was found to be 4.9 nm. These were water dispersible with strong photostability. It was reported that r-FCDs were efficiently taken up by cancerous cells (SW480 and A549) and illuminated the whole cell with a clear distinction between cytoplasm and nucleus. It was revealed that as-prepared r-FCDs can be used as a promising probe for diagnosis and treatment of cancer.

A novel drug delivery system was synthesized by Dong et al. (2018), which was based on arginine−glycine−aspartic acid (RGD)-conjugated GQDs. Later, it was used to load the antitumor drug, DOX for monitoring drug delivery even in the absence of external dyes. It was reported that the release of DOX was strongly pH dependent, which involves hydrogen-bonding interaction between GQDs and DOX as compared to free DOX. It was observed that DOX-GQDs-RGD conjugates exhibited substantial cytotoxicity to U251 glioma cells within a wide range of DOX concentrations. This enhancement combined with efficient nuclear delivery improved the cytotoxicity of the drug DOX on application of GQDs.

A pH responsive nanodrug delivery system was reported by Wang et al. (2018). It was based on ZnO QDs for controlled release of drugs. They introduced poly(2-(dimethylamino) ethyl methacrylate) (PDMAEMA) and zwitterionic poly(carboxybetaine methacrylate) (PCBMA) for modification of

ZnO QDs. These helped in increasing blood circulation time, water stability, and also promoted endocytosis. The DOX (anticancer drug) was successfully loaded on ZnO@P(CBMA-*co*-DMAEMA) with a 24.6% drug loading. As-prepared ZnO@P(CBMA-*co*-DMAEMA) loaded with DOX could achieve lysosomal acid degradation and release DOX after endocytosis by tumor cells, which resulted in a synergistic treatment of cancer by an anticancer effect of Zn^{2+} and DOX, both.

Flak et al. (2018) have studied the preparation of GQDs−mesoporous silica NPs (MSNs) (GQDs-MSNs) nanocomposite as an efficacious intracellular drug delivery system and as a fluorescent factor for optical imaging. GQDs-MSNs nanocomposite NPs composed of GQDs and MSNs were presented as a proficient DOX delivery agent and nontoxic nanocomposite. It has been reported that the effectiveness of prepared GQDs-MSMs nanocomposite NPs for the drug delivery and release next to the bioimaging was analyzed for the case of HeLa cancer cells using a confocal laser scanning microscope and the transmission electron microscopy imaging technique.

Qian et al. (2018) synthesized GQDs hydrothermally and then encapsulated them with supramolecular β-cyclodextrin (β-CD) as a drug delivery system. Two drugs were selected, ranibizumab (Ran) and bevacizumab (Bev), which displayed an initial burst delivery percentage of 52.2% ± 2.6% and 55.7% ± 1.6%, respectively, within the first 15 min. This release from the β-CD encapsulated GQDs reached in a sustained manner 94.2% (Ran) and 93.1% (Bev) of loaded drug molecules after an hour. The biocompatibility of these carriers was evaluated qualitatively as well as quantitatively with the mouse Fibroblast L929 cell line. It was revealed that samples are nontoxic and highly compatible to the cells with >90% cell viability after 5 days of cell culture. The observed results indicate that developed NCs were suitable for the drug delivery system in the AMD.

The fact that graphene (G) is very hydrophobic, whereas GO is decorated by oxygen−containing hydrophilic group, permits both physical and chemical binding of drugs to the surface of G/GO for drug delivery uses (Zhang et al., 2017; Tadyszak et al., 2018; Wychowaniec et al., 2018). The GQDs, which are the most proficient carbon-based nanostructures, have a notable function in biological works (Khosravanian et al., 2021). It has been observed that owing to their small dimension, GQDs present a better perspective in biomedical applications than G or GO and when compared with graphene sheets, GQDs show improved biocompatibility and low toxicity, as promising materials used for the delivery of biologically active loads into living systems (Sangam et al., 2018; Mondal et al., 2019; Fasbender et al., 2019). In recent years, many researchers have shown that GQDs are very encouraging substrates for drug delivery systems. (Li et al., 2019a; Liang et al., 2019; Wang et al., 2019b; Zhao et al., 2020; Jahdaly et al., 2021).

Thovhogi et al. (2018) investigated the use of peptide-functionalized QDs for the imaging of prohibiting (PHB)-expressing cells in vitro and in diet-induced obese rats, which could potentially be used as NCs of antiobesity

drugs, dual targeted drug delivery, and molecular imaging of adipose tissues in obese patients in real time. Abdelhamid et al. (2019) loaded a natural cytotoxic agent (sesamol) onto cadmium sulfide QDs modified chitosan (CTS) to improve its activity. It was found that sesamol-CdS@CTS was more effective against cancer cells as compared to sesamol alone. It was revealed that half maximal inhibitory concentration values (IC_{50}) of CdS@CTS, sesamol, and sesamol-CdS@CTS were 1730 ± 54, 495 ± 16.4, and 117 ± 3.2 $\mu g\ mL^{-1}$, respectively, which indicated that CdS@CTS exhibited high loading efficiency, and can be used for drug delivery.

Triple negative breast cancer (TNBC) is the most fatal type of breast cancer. No targeted chemotherapy is available for the treatment of TNBC because of the absence of progesterone receptor, estrogen receptor, and human epidermal growth factor receptor-2. Ghosh et al. (2019) developed a targeted nonviral vector, which can diagnose TNBC and deliver the gene of interest efficiently. They synthesized carbon QDs from sweet lemon peel and then conjugated it with various generation of polyamidoamine (PAMAM) dendrimers to obtain CD-PAMAM conjugates (CDPs). The RGDS peptide was then further conjugated to CDP to target $\alpha v\beta 3$ integrin. Cellular cytotoxicity, DNA complexation assay, DNase I assay, hemolysis assay, cellular uptake, and in vitro transfection supported the fact that CDP3 is a promising gene carrier system for TNBC gene therapy. The CDP3 also exhibited selective quenching of fluorescence in the presence of Cu(II) with high efficiency (93%). The Cu(II) ion concentration remains upregulated in TNBC. It was predicted that CDP3 could be a promising theranostic tool for the treatment of TNBC.

A multifunctional $(Fe_3O_4/nGO)@mSiO_2/GQDs$ drug transporter, which consists of magnetic core Fe_3O_4, microwave−absorbing nanographene oxide, fluorescent GQDs, and intermediate barrier layer (mesoporous silica), used for loading and microwave-controlled release of an etoposide (VP16) as the anticancer drug, was developed by Wang et al. (2020). The loading rate of VP16 was found to be as high as 68%, and the release rate was observed to be 87% within 280 min.

Alarfaj et al. (2020) synthesized carbon QDs conjugated zinc oxide nanocomposite and used it as highly sensitive fluorescence immunosensing solution for fast determination of CYFRA 21−1 antigen in human serum. They used a hydrothermal method to prepare these QDs using *Citrus limon* pericarp. As-prepared carbon QDs were used to synthesize carbon QDs−zinc oxide nanocomposite by the reduction and stabilization of zinc acetate. As-fabricated immunosensing system based on this nanocomposite (CQDs-ZnO) provided its potential application in rapid diagnoses of lung cancer by detecting CYFRA 21−1 in human serum.

Large doses of anticancer drugs entering cancer cell nuclei are found to be effective for killing cancer cells and increasing chemotherapeutic effectiveness. Red-emitting carbon QDs were reported by Su et al. (2020) that can not only enter into nuclei of cancer cells but also stem cells of cancer.

The DOX was loaded (30 μg mL^{-1}) on the surfaces of carbon QDs. It was observed that average cell viability of HeLa cells was decreased to only 21%, whereas it was decreased to 50% for free DOX. Thus DOX-loaded carbon QDs shows a good therapeutic effect in elimination of cancer stem cells. This has great potential for carbon quantum-dot-based anticancer drug carriers to effectively eradicate cancers.

Nasrollahi et al. (2020) encapsulated GQDs in ferritin protein nanocages to design multifunctional nanoplatforms for cancer therapy and multimodal imaging. Encapsulation of ultrasmall GQDs is expected to reduce their quick excretion from the body and increase their bioimaging efficiency. They encapsulated GQDs and iron inside the core of AfFtn-AA (it is an engineered ferritin nanocage derived from the archaeon *Archaeoglobus fulgidus*). It was achieved through an iron-mediated, self-assembly of ferritin dimers, which afforded GQD−iron complex in the ferritin nanocages, (GQDs/Fe)AA. This (GQDs/Fe)AA showed strong fluorescence at low pH values and high relaxivities in MRI. These were used as a drug nanocarrier and imaging agent. These exhibited negligible cytotoxicity on the MDA-MB-231 cells and a high loading capacity (35%) of DOX. The (GQDs/Fe)AA can find potential applications as MRI agent, drug nanocarrier, and cancer diagnosis and therapy.

Traceable and pH-responsive DDS (MoS_2-PEG-DOX) based on MoS_2 QDs (MoS_2 QDs) was fabricated by Liu et al. (2020a) by covalently grafting MoS_2 QDs with diamine-terminated oligomeric PEG. Then a fluorescent antineoplastic anthracycline drug, DOX was loaded onto it. It was found that MoS_2-PEG-DOX nanoassembly can be effectively taken up by U251 cells, and as a result, enhanced DOX release is then triggered by intracellular acid condition. It reduces or diminishes the undesired side effects derived by the incorporation of DOX into healthy cells. It was concluded that MoS_2-PEG-DOX has a potential for high treatment efficacy in future therapy with minimal side effects.

Felix et al. (2021) decorated the GQDs through carbodiimide crosslinking reaction, where the imatinib molecule, projected to obstruct tyronise kinase, was used to cure leukemia. It has been shown that the integration of the imatinib on the surface of the GQDs did not modify the morphology and the properties of the NPs and that this type of the drug nanoplatform could destroy cancer cells inducing apoptosis. Han et al. (2021) constructed CQDs-based drug delivery system (Arg-Ag@Cu). They used l-arginine as precursor with duplex metal codoping (Cu and Ag) for DOX-loading/releasing and tumor theranostics. It was observed that Ag-doping increased PL intensity while Cu^{2+} could act as an anchor resulting in adjustable size of CQD for increasing the drug loading capacity. It was revealed that the structure of Arg-Ag@Cu was disrupted due to Cu^{2+} depletion, which supported in situ DOX-releasing. It was also revealed that there were synergistic effects, which suppressed tumor progression and migration with relatively no or minimal side effects.

Liu et al. (2021) presented some GQDs functionalized with polyethyleneimime (PEI) as a new messager RNA (mRNA) delivery system demonstrating that these modified GQDs can be utilized to provide intact and functional mRNA to Huh−7 hepatocarcinoma cells at low quantities and that these functionalized GQDs can be considered as ideal delivery system. Ruzycka-Ayoush et al. (2021) used Ag−In−Zn−S QDs modified with L-cysteine, 11-mercaptoundecanoic acid, and lipoic acid decorated with FA. It was then used as a novel target drug delivery system for targeting DOX to folate receptors on adenocarcinomic human alveolar basal epithelial cells (A549).

It has been shown that GQDs are materials capable of responding to physical stimuli, such as magnetic fields, ultrasound, and light, and this fact permitted the precise control of drug release (Dai et al., 2017; Gu et al., 2019; Liu et al., 2021). Some researchers have reported that small molecule-modified GQDs could be used for simultaneous cellular drug delivery imaging, modifying GQDs with arginine−glycine−aspartic acid (RGD) (Qiu et al., 2015) and FA (Wang et al., 2014), explaining that the antitumor drug DOX-loaded RGD- or FA-modified GQDs could not only transport drugs to target cells, but supervise the cellular operation uptake of the drug in real time without using external dyes (Wang et al., 2017).

11.4 Sensing

It has been established that biotechnology, in combination with nanotechnology, provides the enhanced evolutionary biological components needed to create novel smart sensors and advanced characterization and manufacturing mechanisms to solve environmental and biological problems (Ray et al., 2009; Choi and Montemagno, 2016).

A selective chemiresistive gas sensor for detection of carbon dioxide at room temperature (~25°C) was prepared by Rathi and Pal (2020). It contains ruthenium-decorated tungsten disulfide (Ru@WS_2) QDs as the sensing material. They used a mixed solvent of lithium hydroxide and N-methyl-2-pyrrolidone (NMP) to prepare Ru-decorated WS_2 QDs from the exfoliated WS_2 nanoflakes. The gas sensors were fabricated by spraying the QDs (WS_2 QDs and Ru@WS_2 QDs) on gold interdigitated electrodes, which were then exposed to different concentrations of CO_2 gas in dry air conditions. It was reported that Ru@WS_2 QD-based sensor exhibit superior sensitivity and good selectivity to CO_2 gas as compared to WS_2 QD to isopropanol, acetone, ethanol, methanol and benzene at room temperature. This sensor showed an increase in resistance when it was exposed to CO_2 gas ranging from 500 to 5000 ppm.

Bhatt et al. (2020b) performed some excellent approaches, which present all significant aspects of QDs properties. Such unique properties have been created for successful applications, which comprise photodetectors, photovoltaic devices, photocatalysis, biosensors, chemical sensors, displays, photodynamic therapy,

laser diodes, and so on. Due to their special PL and electrochemical features, GQDs are among the most interesting carbon-based NMs used to fabricate biosensors (Xie et al., 2016).

In accordance with the technique that is applied, GQDs-based sensors can be classified into the following broad groups: PL sensors, chemiluminescence (CL) sensors, and electrochemical (ECL) sensors; these QDs-based sensors and biosensors provide a plethora of opportunities to diagnose an extensive range of diseases and improve therapeutic actions (Henna and Pramod, 2020).

Bhakat et al. (2021) developed a facile method to prepare ZnO QDs into three-dimensional superstructures through surface complexation between zinc ions and phosphate. It was reported that the addition of phosphate to ZnO QD dispersion led to growth of such parahopeite structures along with crystalline assembly of QDs in the colloidal medium. It was revealed that the as-prepared ZnO QD−phosphate crystalline assembly can be successfully applied to fabricate a gas (CO_2) sensor, which exhibited great selectivity and sensitivity toward carbon dioxide gas at room temperature.

11.4.1 Photoluminescence sensors

A new, simple and highly sensitive PL evaluation method for the activity of a protein kinase depending on the selective aggregation of the phosphorylated peptide-GQD conjugates triggered by Zr^{4+} ion coordination was proposed by Wang et al. (2013b). The developed technique has revealed some feasible uses in kinase inhibitor screening. The inhibition of CK2 phosphorylation activity by four various inhibitors was examined in human serum by analyzing the signals from samples incubated with and without any inhibitors. It was revealed that PL intensity was enhanced by improving the efficiency of the inhibitor.

Sun et al. (2013) presented various methods and some future prospects for the progress of the smart sensing platform based on GQDs, showing that GQDs, which are produced using diverse procedures, can emit PL with different colors and in these GQDs, PL is controlled by numerous parameters, such as size, shape, excitation wavelength, pH, concentration, surface oxidation degree and surface functionalization.

A precise technique for the preconcentration and the determination of GO in natural river water samples utilizing fluorescent GQDs was studied by Benitez-Martinez et al. (2014). The functioning of the presented GQDs sensor is related to the interaction between GO and GQDs via hydrophobic $\pi-\pi$ stacking of the GO with aromatic network at the GQDs surface; this fact causes a quenching effect of the fluorescence of GQDs, that was used as an investigative indicator for their quantification. The LOD was calculated to be $35\,\mu g \cdot L^{-1}$. It was reported that the precision for a $200\,\mu g \cdot L^{-1}$ concentration of GO was found to be 5.16%.

Benitez-Martinez and Valcárcel (2015) reviewed the principal analytical uses of GQDs, highlighting more details on the progress of various categories of sensors, which are used to detect metal ions, small organic molecules and biomaterials with enhanced sensitivity. They have shown that GQDs are recent materials for designing and tuning sensors (and biosensors) and they focused mostly on the presentation of some important analytical applications in the field of PL-based sensors.

Zor et al. (2015) studied the synthesis and characterization of a new multifunctional composite material, magnetic silica beads/GQDs/molecularly imprinted polypyrrole (mSGP), where mSGP is designed to capture and signal small molecules; thanks to the synergy among chemical, magnetic, and optical attributes that are connected with the molecular printing of tributyltin. It was observed that the studied multifunctional material allowed a fast and highly sensitive scaffold for small molecules detection even in complex media such as seawater without any sample treatment.

All-inorganic cesium lead halide ($CsPbBr_3$) perovskite QDs, as one kind of promising material, have attracted considerable attention in optoelectronic applications. Colloidal $CsPbBr_3$ QDs were synthesized by Chen et al. (2017a) by adjusting the reaction temperatures with tunable PL (493−531 nm). It revealed narrow emission bandwidths of 25 nm. Average diameters of the QDs were calculated and it was found that this could be adjusted from 7.1 to 12.3 nm on increasing temperature from 100°C to 180°C. They also fabricated green LEDs using $CsPbBr_3$ QDs cast on blue LED chips, which have a great potential for applications in the field of lighting technology and display.

Quaternary $Zn_xAgInSe$ QDs were synthesized by Ding et al. (2017) with different Zn/Ag ratios. These were then evaluated as temperature sensors. A correlation between different temperatures and emission intensity, luminescence energy, and full-width at half-maximum of the emission band was observed; where only a small deviation was observed from the actual temperature, indicating that $Zn_xAgInSe$ QDs can be used as temperature sensors with high sensitivity.

Duran et al. (2017) presented a modern, rapid, inexpensive, and acid treatment procedure for the synthesis of copper-modified GQDs. Then this was used for the quantification of penicillamine (PA) in pharmaceutical samples using interaction of the drug with Cu-modified GQDs (Cu−GQDs). It was reported that under the best conditions for interaction, a linear response was remarked (in the concentration range 0.10−7.50 pmol L^{-1} PA) and the viability of the recommended fluorescent sensor has been demonstrated.

The $CsPbBr_3$@Ag hybrid nanocrystals were synthesized by Ye et al. (2017). They treated $CsPbBr_3$ nanocrystals with silver halides (Cl, Br, or I) powders in hexane for this purpose. It was indicated that particle size of Ag NPs varied between 2 and 5 nm and these were nucleated randomly outside these hybrid $CsPbBr_3$ nanocrystals. An enhanced PL intensity of $CsPbBr_3$@Ag hybrid nanocrystals was observed as compared to $CsPbBr_3$ nanocrystals under the light of

400 nm, to achieve an enhanced PL. They optimized $CsPbCl_xBr_{3-x}$@Ag hybrid nanocrystals so that the effect of plasmonic resonance enhancement occupied a significantly advantageous position. It was suggested that as-constructed $CsPbBr_3$@Ag hybrid nanocrystals can find new opportunities for application in optoelectronic devices and LEDs.

Sahub et al. (2018) developed a novel real-time biosensor of GQDs-based enzymatic reaction (GQDs AChE/CHOx) for monitoring the organophosphate (PO) pesticides. It was observed that H_2O_2 created from the active enzymatic reaction of acetylcholinesterase (AChE) and choline oxidase (CHOx) allowed to react with GQDs inducing a "turn-off" PL of GQDs. The limit of detection of this biosensor was calculated to be 0.172 ppm (0.778 μM). The suggested biosensor was successfully applied for the determination of dichlorvos, utilizing a reduced price procedure via a connection with green chemistry approach.

Xu et al. (2018) produced a high PL quantum yield for transition metal carbide (2D) MXene (nitrogen-doped, N-doped Ti_3C_2) QDs. They used Ti_3C_2 and ethylenediamine as a precursor and nitrogen source, respectively. The average size of hydrothermally treated N-doped Ti_3C_2 QDs was 3.4 nm and PLQY of up to 18.7% was observed. As-prepared N-doped Ti_3C_2 QDs were then used as an ultrasensitive detector probe for iron ion (Fe^{3+}) with a limit of detection up to 100 μM. It was also reported that as-developed MXene QDs can find application in biological sensing for detection of H_2O_2 with high sensitivity. These QDs have a lot of applications such as solar cells, electronics, biomedical, optical, photocatalysis, biosensors, white light emission devices, and environmental fields.

Li et al. (2019b) introduced a stoichiometry control over both; core and shell regions of InP/ZnSe/ZnS QDs. As-obtained QDs exhibited PL quantum yield (almost approaching 1), narrow line width, monoexponential decay dynamics and nonblinking at a single-dot level. These quantum-dot LEDs (QLEDs) based on InP/ZnSe/ZnS core/shell/shell QDs are good emitters exhibiting a peak external quantum efficiency (12.2%) and a maximum brightness ($>10\ 000\ cd\ m^{-2}$), which is more than Cd/Pb-free QLEDs. It was revealed that these Cd/Pb-free QDs can prove to be outstanding optical and optoelectronic materials.

11.4.2 Chemiluminescence sensors

The L-cysteine capped CdS QDs were prepared by Hassanzadeh et al. (2017) via a hydrothermal route. It was found that as-prepared CdS QDs show a significant effect on the CL reaction of the rhodamine B (RhB)-cetyltrimethylammonium bromide (CTAB)-$KMnO_4$ system. It was also found that CL emission intensities of these QDs exhibited a change in the presence of methamphetamine (MA) (even in low quantities). It was observed that MA can remarkably increase the intensity of CL system and this improved CL intensity was found to be proportional to MA concentration in the range of

0.25−125 ng mL^{-1} with a limit of detection of 0.086 ng mL^{-1}, which was more than 20 times higher than the FL method. The as-developed CL method was used for accurate determination of MA in real samples (human urine).

The *N*-(Aminobutyl)-*N*-(ethylisoluminol)/(ABEI) functionalized GQDs (ABEI-GQDs) with outstanding CL and FL attributes were synthesized by Gao et al. (2017). They observed that as-synthesized ABEI-GQDs exhibited exceptional CL features, when reacted with H_2O_2 and wavelength−tunable FL emission with increasing excitation wavelength. They built a pesticide−sensing array for pesticide differentiation using their CL and FL properties. It was reported that new CL and FL dual-signal GQDs (ABEI−GQDs) have been developed, which could find more interesting future uses in bioassays and bioimaging.

Khataee et al. (2018) developed a modern and high CL system using the promoting effect of GQDs/bisulfite on rhodamine B(RB)−H_2O_2 CL reaction. It was reported that the existence of sodium dodecyl sulfonate (SDS) and sodium bisulfite resulted in a much improved action of GQDs. It was recalled that the International Agency for Research on Cancer and the Environmental Protection Agency estimated the cancer risk of formaldehyde (HCHO) on human and classified this compound as carcinogenic (Lobo et al., 2015; Khataee et al., 2018). This CL system, which is dependent on the oxidation of rhodamine B, has been shown to be a successful chemosensor for HCHO, noting that HCHO can decrease the developed CL system. It was found that a linear change of the CL response was achieved in HCHO concentration ranges of 0.02−5 and 5−11 μg L^{-1} with a limit of detection and quantification of 6 and 20 ng L^{-1}, respectively.

The captivating contribution of GQDs in introducing sensors is due to the fact that they can be used as a luminescent donor, energy acceptor, or amplification (catalyst) pathway for the system of CL resonance energy transfer (CRET), enhancing the sensitivity of detection (Pang et al., 2018; Chen et al., 2020). Pang et al. (2018) showed that GQDs could notably improve the CL reaction of Ce(IV) with $NaHSO_3$ using energy and electron transfer. It was observed that the CL intensity of the GQDs-Ce(IV)-$NaHSO_3$ model was inhibited by tyrosine (Tyr), which has a significant function in the metabolism and growth of human and animals. The recommended (CRET) method can be successfully used for Tyr evaluation in milk samples with a high precision.

Irani-Nezhad et al. (2019) synthesized WS_2 QDs through solvothermal method. As-obtained WS_2 QDs had a size of 1−1.5 nm with fluorescence emission depending on excitation wavelength. These WS_2 QDs show a catalytic effect in the decomposition of H_2O_2. As-prepared WS_2 QDs exhibit a mimetic effect in the H_2O_2−rhodamine B CL system. The H_2O_2 is one of the products in the enzymatic reaction of glucose, which can be easily determined using WS_2 QDs. It was reported that H_2O_2 can be detected in the concentration range (0−1000 nmol L^{-1}) with a limit of detection as 2.4 nmol L^{-1}.

Vahid et al. (2019) developed a method for the sensitive determination of cyanide ions (CN^-) in biological as well as environmental samples. They used a CRET-induced CL system for this purpose. Hydrogen peroxide−bicarbonate system was selected for CL reaction. It was reported that glutathione-stabilized CdSe QDs (CdSe QDs) increase CL intensity significantly. On the contrary, it was observed the CRET system could be prohibited and CL emission turned off by gold nanoclusters (Au NCs). On efficient dissolution of Au NCs, the CRET to CdSe QDs was restored and CL emission was turned on. It can be used as a highly sensitive and reliable measurement of cyanide ions in the concentration range of 2−225 nM, with a limit of detection of 0.46 nM.

Hallaj et al. (2020) prepared S,N-doped carbon QDs (S,N-CQDs) via a hydrothermal method. They observed effect of as-prepared CQDs on the luminol−Mn(IV) CL reaction and it was found that S,N-CQDs increased the CL intensity of this reaction about 13-fold. It was also revealed that the CL intensity of this system was drastically reduced in the presence of uric acid. They designed a probe for the detection of uric acid using the amplified CL system and it was observed that it was proportional to the logarithm of uric acid concentration in the range 0.05−1.5 μM with a detection limit of 17 nM. Thus they developed a sensitive CL method for the detection of uric acid in biological fluids.

Rasoulzadeh and Amjadi (2021) prepared highly luminescent water-soluble $AgInS_2$ QDs (AIS QDs) via a green and hydrothermal method. It was reported that $NaIO_4$ in alkaline solution elicits a remarkable CL from as-prepared QDs. It was also revealed that the addition of glutathione to this $NaIO_4$-AIS QDs system enhanced CL intensity effectively, and therefore it was used as a sensing platform for the assay of GSH. It was reported that there is a relation between GSH concentration and CL intensity, which was linear in the range (1.0×10^{-9} mol L^{-1} to 5.0×10^{-6} mol L^{-1}) with a limit of detection of 2.8×10^{-10} mol L^{-1}. They also confirmed its usefulness in the analysis of human plasma.

Yahyai et al. (2021) developed a paper-based analytical device integrated with a potent CL system to find out deltamethrin (DM), using the enhancing effect of polyphosphate (PP) on GQDs-$KMnO_4$ CL reaction. They showed that the realized multiemission CL structure was investigated for analytical applications. It was revealed that under the optimized conditions, the generated signal is reduced by increasing the DM concentration in the range of 0.3−10 μg mL^{-1} with LOD as 0.15 μg mL^{-1}. This can be presented as an advanced analytical detection technique determination for DM in food samples, for on-site screening scopes.

11.4.3 Electroluminescence sensors

A high sensitivity label-free ECL immunosensor has been constructed by Wu et al. (2016) for the detection of prostate−specific antigen (PSA) based on GQDs. They used Au/Ag-rGO as electrode material to load the amounts

of aminated GQDs and carboxyl GQDs to amplify the ECL signal. The developed methodology shows that the ECL intensity decreased linearly with the logarithm of PSA concentration and the LOD is 0.29 pg mL^{-1}. The immunosensor can be successfully utilized in disease and drug analysis.

Shan et al. (2016) proposed CdS QDs as electrochemical sensing materials for determination of ciprofloxacin (CIP). It was reported that CdS QDs-modified glassy carbon electrode (GCE) exhibited a good anodic stripping response in acidic medium, which was attributed to the release of Cd(II) ions from CdS QDs. It was observed that anodic stripping current of Cd(II) on CdS QDs/GCE was found to decrease in solution, when CIP was added, which may be due to the complexation of CIP with in situ generated Cd(II) ions. A linear relationship was obtained between the anodic stripping voltammetric response of CdS QDs/GCE and concentration of CIP in the range (1.0×10^{-7}–1.0×10^{-5} mol L^{-1}) with a limit of detection as 2.2×10^{-8} mol L^{-1}. The use of CdS QDs-modified electrode for determination of CIP was observed in biological fluids.

The black phosphorus QDs (BPQDs) were synthesized by Ding et al. (2018) and then added into the solution of ZnO nanorods to obtain BPQDs-doped ZnO NPs (BPQDs@ZnO). They used a hydrothermal route for this purpose. The doping of BPQDs resulted in the formation of cubic BPQDs@ZnO NPs. The ECL of BPQDs@ZnO was investigated under neutral conditions. They obtained a cathodic ECL signal in the presence of $K_2S_2O_8$ that is relatively stronger than for ZnO nanorods. It was observed that cytochrome c exhibited an inhibiting effect on BPQDs@ZnO ECL, which can be sensitively detected in the range of 1.0×10^{-9}–5.0×10^{-7} mol L^{-1} with a limit of detection as 9.6×10^{-10} mol L^{-1}. It was revealed that such ECL characteristic of BPQDs-based nanocomposite has a potential in biosensing application.

Jie et al. (2019) developed an innovative procedure for amplified ECL detection of DNA utilizing the magnificent ECL activity of GQDs combined with a multiple cycling amplification mechanism. They used a novel poly (diallyldimethylammonium chloride) (PDDA)-GO complex to immobilize GQDs on the electrode to improve the ECL signal. This method is based on ECL quenching of Au NPs to GQDs combined with endonuclease aided cyclic amplification scheme, which has good application perspective in biosensing research, mainly in clinical diagnoses.

Wang et al. (2019a) reported a novel highly sensitive cloth-based closed bipolar ECL (C–BP–ECL) sensor with nanostructured electrode surface. The proposed method is based on the combination of chitosan (CS), poly (diallyldimethylammonium chloride)-functioned multiwalled carbon nanotubes (PDDA-MWCNTs), and GQDs–gold NPs (GQDs–AuNPs/PDDA) on the wax/carbon ink-screen-printed cloth-based device. The combination of GQDs–AuNPs-MWCNTs/CS, C-BP-ECL, and cloth-based microfluids for the detection of highly sensitive glucose has been established for the first

time, showing that glucose concentrations in complex human serum samples can be determined with this technique.

A novel ultrasensitive ECL sensor was studied by Niu et al. (2020) that can be used to detect a common food additive (sunset yellow). They used GQDs as the luminescent factor and potassium persulfate as the coreactant, showing that the ECL signal of the GQDs changed with the inclusion of sunset yellow. It has been observed that this method provides fast screening of possibly harmful food additives and, under optimized conditions, the GQD sensor exhibits a good linearity in the detection of sunset yellow in the concentration range of 0.0025−25 μM with a LOD as 7.6 nM.

de França et al. (2021) modified graphite working electrode (5 mm diameter) with CdSe/CdS magic-sized QDs (MSQDs) to increase its sensitivity. This modified electrode was fully characterized and optimized. It was reported that the best results were obtained when MSQDs (10 μg) were deposited on the electrode surface. It was revealed that a QDs-based sensor exhibited good stability, reproducibility, and repeatability. Such an electrochemical sensor was used for detecting dopamine. The signal showed dependence in the concentration range 0.5−15 $\mu mol\ L^{-1}$ with a limit of detection of 96 $nmol\ L^{-1}$. This was also successfully used for sensing of dopamine in real samples (human blood serum) with recovery rates ranging between 95.2% and 102.6%.

11.5 Others

Shao et al. (2012) linked most the promising suicide genes (herpes simplex virus thymidine kinase, HSV-TK gene) with CdTe/CdS core/shell QDs using the EDC/NHS coupling method. It was reported that plasmid TK intracellular trafficking can be distinctly and effectively traced via monitoring QDs' luminescence for up to 4 days after transfection of QDs-TK conjugates into Hela cells. It was observed that QDs-TK conjugates have more efficient cytotoxicity on addition of GCV into Hela cells, and these QDs do not show any detectable adverse effects on the cellular processes. It was revealed that photonic NMs (QDs) can be used as a tool for monitoring TK gene delivery and anticancer activity.

Ng et al. (2013) investigated cell-based cytotoxicity of N-acetyl-cysteine (NAC) QDs and also the effect of QDs on the beta (1−40) amyloid ($A\beta_{1-40}$)-induced cytotoxicity on human neuroblastoma SH-SY5Y cells by MTT (3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide) and reactive oxidative species (ROS) assays, respectively. It was reported that the inhibition of $A\beta_{1-40}$ peptides from fibrillation using NAC−QDs had a neuroprotection effect on the neural SH-SY5Y (neuron) cells.

Shao et al. (2014) also reported a QD-based technique that revealed a method of herpes simplex virus thymidine kinase (HSV-TK) suicide gene therapy by forming a covalent linkage between the TK gene and NIR fluorescent QDs. It was interesting to note that stable QD labeling did not affect

either the biological activity of the TK gene or QDs fluorescence. They traced the intracellular behavior antitumor effect of the TK gene in vivo and in vitro. It was revealed that the TK gene was shuttled to the nucleus after 24 h treatment. A single dose of GCV administration at that time exerted a gradually increasing lethal effect for 72 h. It was proposed that this technique may be useful for cancer therapy in the future.

Weng et al. (2015) synthesized mannose-modified fluorescent carbon QDs (Man-CQDs) via a simple one-step dry heating method from solid ammonium citrate and mannose. It was reported that highly soluble Man-CQDs had average particle diameter of 3.1 ± 1.2 nm. It can be successfully applied for labeling *Escherichia coli*. The labeling efficiency of Man-CQDs can be optimized by controlling the ratio of ammonium citrate/mannose. They demonstrated that quantitative detection of the bacteria *E. coli* (450 CFU) is possible because of specific binding of the mannose units to *E. coli* in lab samples, and it can be also applied to real samples (tap water, human urine, and apple juice).

Magnesium and nitrogen codoped carbon QDs (Mg-N-CQDs) were prepared by Liu et al. (2016) via a hydrothermal method. It can be used as a fluorescent switch for selective and sensitive sensing of Hg(II) and cysteine (Cys). The fluorescence of Mg-N-CQDs aqueous solution was quenched on addition of Hg(II) and it has been attributed to the formation of a nonfluorescent complex between Mg-N-CQDs and Hg(II). But the fluorescence of these QDs aqueous solution containing Hg(II) could be recovered back in the presence of Cys in a gradual manner, as Hg(II) has stronger binding affinity toward Cys than toward Mg-N-CQDs. They designed a fluorescent probe and applied it to detect Hg(II) ions in real water samples with satisfactory results.

A green hydrothermal strategy has been devised by Bao et al. (2018) to produce water-soluble nitrogen/phosphorus (N/P) codoped CQDs using edible *Eleocharis dulcis*. As-prepared CQDs exhibited high quantum yield, remarkable excitation-dependent emission, long lifetime, and superior fluorescence stability. The N/P codoped CQDs had a wide-range capability to determine inorganic cations as fluorescence sensor. They showed remarkable selectivity and sensitivity for Fe^{3+} ions.

Kumari et al. (2018) used the residue obtained from the pyrolysis of waste polyolefins, for preparing highly green-visual fluorescent carbon QDs via a simple one-step hydrothermal approach, which consists of ultrasonic-assisted chemical oxidation. The use of as-synthesized CQDs as a fluorescent sensor for Cu^{2+} ions detection was investigated, where excellent sensitivity and selectivity were exhibited for detecting Cu^{2+} ions with a limit of detection of 6.33 nM in the detection range of $1-8.0\,\mu M$. It was also revealed that these CQDs show their use in the analysis of real water samples. Apart from this, CQDs have the potential for TNBC cells (MDA-MB 468 cells) imaging.

Xiang et al. (2018) conjugated FA onto the surface of ZnO QDs (QDs)-NH_2 via an amidation reaction. As-prepared titania nanotubes (TNTs) loaded with vancomycin (Van) are capped by these FA-functionalized ZnO (ZnO-FA) QDs. This arrangement keeps them stable in normal physiological environments, but dissolves as Zn^{2+} in the mildly acidic environment after bacterial infections. The antibacterial ratio of TNTs-Van@ZnO-FA QDs against *Staphylococcus aureus* was increased from 60.8% to 98.8%, while it only increased from 85.2% to 95.1% for TNTs-Van, when the pH of the environment was decreased from 7.4 to 5.5. It was suggested that this surface system has a promising bioplatform on Ti-based metallic implants as it prevents bacterial infection with a long-lasting effect. It is suitable for various applications like antifungal, antibacterial, antiinflammatory, antioxidant, and wound healing.

Murugan et al. (2019) developed facile, rapid and frugal approach for the synthesis of highly fluorescent carbon QDs by pyrolysis of finger millet ragi (*Eleusine coracana*) (carbon source). It was found that the size distribution was in the range of 3−8 nm. It was indicated that Cu^{2+} strongly quenched the fluorescent intensity of these CQDs as compared to other metal ions such as Mg^{2+}, Pb^{2+}, Ni^{2+}, Mn^{2+}, Hg^{2+} Al^{3+}, Ca^{2+}, and Cr^{3+}. A linear correlation was observed between quenching efficiency concentration of Cu^{2+} ions in the range from 0 to 100 μM. These CQDs were also applied in sensing of Cu^{2+} in real water samples and the limit of detection was 10 nM. It was found that Ni^{2+} and Cu^{2+} formed a very strong bonding with CQDs compared to other divalent ions. It was revealed that Cu^{2+} get adsorbed on aromatic C═C (π-bond) of CQDs preferentially while other divalent metals form σ-bond(s) with the CQDs.

An easy and economical synthesis of highly fluorescent nitrogen-rich carbon QDs (N-CQDs) was reported by Bao et al. (2019). It was observed that as-prepared N-CQDs can act as a sensor for the "turn-off" detection of Co^{2+} in the range of 0.5−3 μM with a detection limit of 0.12 μM. The fluorescence of the quenched N-CQDs was formed to reappear and get "turn-on," when GSH, AA, EDTA, and cyst were used. It was claimed that N-CQDs were also successful in detecting the trace level of Co^{2+} in vitamin B_{12} sample.

Fluorescent QDs with optical properties (such as tunable broad excitation, robust photostability high quantum output, and restricted emission spectra) are utilized as a new class of optical probe in biological and biomedical fields (Jahangir et al., 2019). Lei et al. (2019) proposed an eco-friendly synthetic procedure to prepare emission-tunable carbon QDs. The particle size of as-synthesized CQDs was found to be 2.4 nm. Significant properties of controllable emission make these QDs a potential candidate for sensor applications.

Chandra et al. (2020) developed a fast and eco-friendly one-pot hydrothermal technique for synthesizing nitrogen/sulfur-codoped fluorescent carbon QDs (NS-CQDs). They used simple precursors such as citric acid and thiosemicarbazide. The as-prepared NS-CQDs were used successfully as a

nanoprobe for detecting picric acid (PA) in different derivatives. It was also reported that this system exhibited low cytotoxicity and excellent biocompatibility in HeLa cervical cancer cells. It was reported that it can be used for the detection of PA in environmental, analytical, and pathological applications.

GQDs have low cytotoxicity and higher biocompatibility as compared to other QDs, The optical properties of QD and have the ability to cross the blood−brain barrier, and therefore GQDs can be useful in neuroscience diagnostics and therapeutics. Their smaller size, surface chemistry and ease of loading of different drugs make them potential drug delivery systems as they could travel through the bloodstream up to the brain. Perini et al. (2020) discussed the applications of GQDs in drug delivery to the central nervous system, bioimaging, and photophysical therapies.

Kateshiya et al. (2020) proposed a synthetic route for the preparation of highly blue fluorescent tyrosine coated molybdenum oxide QDs (Tyr-MoO_3 QDs). Here, tyrosine (Tyr) was used as a surface ligand to functionalize MoO_3 QDs. They obtained color changes in the solution of MoO_3 NPs, MoO_3-OH NPs and Tyr-MoO_3 QDs in presence of UV and day light. It was reported that as-prepared Tyr-MoO_3 QDs could act as a sensor for rapid and sensitive identification of imidacloprid. It was revealed that emission peak of Tyr-MoO_3 QDs at 416 nm exhibited a linear quenching on increasing concentration of imidacloprid in the range (0.045−1.00 μM). The proposed method was successfully applied for the detection of imidacloprid in real samples also.

The activities of ions are closely associated with the physiology of brain such as neural activity, intracranial cell membrane potential, and neuropathology. Therefore, monitoring the levels of ion in the brain is of utmost importance in neuroscience. A powerful tool has emerged as nanosensors for monitoring brain ion levels, cell function, neural activity, and it can also be used in the diagnosis of diseases. The advances in the design and application of these ion level nanosensors at different physiological levels have been reviewed by Wei et al. (2020).

Jlassi et al. (2021) prepared GQDs from graphitic waste. These GQDs were evaluated as resistive humidity sensors. Such resistive humidity sensors were fabricated on the prepatterned interdigital indium tin oxide electrodes with three different concentrations (2.5, 5.0, and 10 mg) of GQDs in N, N-dimethylformamide (DMF). It was observed that GQDs (10 mg mL^{-1})-based impedance sensors exhibited good sensitivity as compared to the other ratios (2.5 and 5 mg). They reported that the maximum calculated hysteresis of the GQDs-based humidity sensor was found to be around 2.2% at 30%RH while the minimum was 0.79% at 60%RH. It was revealed that response and recovery time were 15 s and 55 s, respectively.

11.6 Toxicity of quantum dots

Yan et al. (2011) investigated the potential vascular endothelial toxicity of QDs, particularly of mercaptosuccinic acid-capped CdTe QDs in vitro. They

synthesized pH stable and water-soluble CdTe QDs and their cell viability were tested. The presence of CdTe QDs ($0.1-100\ \mu g\ mL^{-1}$) decreased the cell viability of human umbilical vein endothelial cells (HUVECs), which indicated that these QDs induced significant endothelial toxicity. It was also revealed that CdTe QDs ($10\ \mu g\ mL^{-1}$) exhibited mitochondrial network fragmentation, significant oxidative stress, and disruption of mitochondrial membrane potential. It was suggested that these QDs not only impaired mitochondria but also induced endothelial apoptosis and exerted endothelial toxicity, providing strong evidence of the direct toxic effects of QDs on human vascular ECs, and indicating that exposure to QDs is a significant risk for the development of cardiovascular diseases.

Smith et al. (2012) selected primary human liver (PHL) cells and HepG2 cells as in vitro tissue culture models to observe the possible adverse effects of copolymer-coated CdSe/ZnS QDs poly(maleic anhydride-*alt*-1-tetradecene) (TOPO-PMAT copolymer CdSe/ZnS QDs) (when TOPO = tri-*n*-octylphosphine oxide) and PMAT. However, PHL cells did not take up TOPO-PMAT CdSe/ZnS QDs, but some nonparenchymal cells did, particularly Kupffer cells. No acute toxicity or morphological change was noted in these systems up to 40 nM. It was observed that cellular stress markers and proinflammatory cytokines/chemokines were increased in PHL cell cultures, which suggests that these QDs are not likely to cause acute cytotoxicity in the liver but may elicit inflammation or hepatitis.

Liu et al. (2015) evaluated cytotoxicity of four types of QD formulations (PEGylated phospholipid encapsulated CdSe/CdS/ZnS QDs (CdSe-Phos), MPA modified CdSe/CdS/ZnS QDs (CdSe-MPA), Pluronic F127 encapsulated CdTe/ZnS QDs (CdTe-F127), and PEGylated phospholipid encapsulated InP/ZnS QDs (InP-Phos)) in two different human cancer cell models (neuroblastoma (SH-SY5Y), gastric adenocarcinoma (BGC-823) cell lines).

Wang et al. (2016) reviewed the toxicity of GQDs, including raw GQDs, chemically doped GQDs, and chemically functionalized GQDs and also presented some important details related to the uptake process by cells and parameters managing the toxicity of GQDs (concentration, synthesis methods, particle size, and surface chemistry). Various issues related to the toxicity regulation of GQDs through chemical modification were discussed, exposing some important aspects about the toxicity mechanism through generation of ROS by some GQDs.

Xiao et al. (2016) studied the cytotoxicity of two types of QDs on *Chlorella pyrenoidosa* at different concentrations:

- carbon QDs (CQDs): Undoped CQDs, N-doped CQDs, N,S-doped-CQDs; and
- metal QDs (MQDs): CdS QDs, CdTe QDs, $CuInS_2$/ZnS QDs.

The Chla contents were found to be consistent to the number of algae cells, when *C. Pyrenoidosa* was treated by different concentrations of QDs.

It indicates a good dose-response relationship. The EC_{50} of undoped CQDs, N-doped CQDs, N,S-doped CQDs, CdS QDs, CdTe QDs, and $CuInS_2$/ZnS QDs was observed as 232.47, 185.83,38.56, 4.88, 0.015, and 459.5 mgL^{-1}, respectively at 96 h. They observed toxicity order as follows:

$CuInS_2$/ZnS QDs <Undoped CQDs <N-doped CQDs <N,S-doped CQDs <CdS QDs <CdTe QDs.

It was concluded that the toxicity of CQDs was relatively less as compared to MQDs, but $CuInS_2$/ZnS QDs exhibited the lowest toxicity.

The toxicity of NMs is one of the crucial challenges facing their use in biotechnology (Chen et al., 2017b). The growing biomedical domain of G-based material applications, including GQDs, raises some queries about their short- and long-term cytotoxicity (Tadyszak et al., 2018).

A comparison of the toxic effects was made by Pramanik et al. (2018) between CdSeQDs, silicon QDs, and CdSe/ZnS QDs. They selected two model bacteria: Gram-negative bacterium (*Shewanella oneidensis* Mr-1) and a Gram-positive bacterium (*Bacillus subtilis* SB 491). It was indicated that the silicon QDs not associated with the cell membranes are benign to these bacteria. On the other hand, CdSe cores exhibited significant toxicity to these bacteria while CdSe/ZnS QDs are relatively less toxic.

Deng et al. (2018) have utilized the Illumina high-throughput RNA sequencing to examine the whole-transcriptome profiling of zebrafish larvae after exposure to GQDs, identifying 2116 differentially expressed genes between GQDs exposed groups and control. Zebrafish is a preferred type of an organism for toxicity testing due to its small dimension, reduced maintenance price, and optical transparency (Grunwald and Eisen, 2002; Hill et al., 2005; Dai et al., 2014; Sonthanasamy et al., 2016; Chen et al., 2016; Tang et al., 2017; Deng et al., 2018; Liu et al., 2020b).

Little is known about the developmental disturbance in animals after GQDs exposure at some concentration values that are higher than the tolerable level (Deng et al., 2018). It has been reported that the acute inflammatory responses and detoxifying complex represent the principal GQDs-activated pathways and that GQDs can perturb the blood homeostasis via upregulating the renin−angiotensin system structure. Some results related to the molecular processes of possible bleeding risks and detoxifying operations have been reported as an effect to GQDs exposure.

Nikazar et al. (2020) pointed out that even if the latest classes of new manufactured QDs exhibit ever-better physical properties, some details related to their cytotoxicity are some major drawbacks, and in order to address the challenges of QD research it is vital to examine the type of the characteristics that make these QDs toxic. They also reviewed changes in toxicity of GQDs, when they are in association with other metal ions.

Gu et al. (2021) developed highly fluorescent Ti_3C_2 and Nb_2C MXene QDs for labeling of in vitro models cytotoxicity of the QDs to human umbilical vein endothelial cells HUVECs. It was observed that a significant

cytotoxicity was induced on exposure by 100 μg ML^{-1} Ti_3C_2 but Nb_2C QDs could not exhibit it even after 24 h. It was also revealed that Nb_2C QDs were found to be more biocompatible to HUVECs as compared to Ti_3C_2 QDs at the same mass concentrations.

The in vitro toxicity of $CuInS_2$/ZnS QDs was investigated by Xue et al. (2022) on U87 human glioma cell line. It was observed that these QDs enter the cells and are located mainly in the cytoplasm. It was reported that 1515 genes were downregulated and 220 genes were upregulated, which significantly changed gene functions, including chromosome-DNA binding, nucleosome, and chromosome assembly.

11.7 Conclusion

This chapter furnishes a complete overview of the most recent emerging advances in the research domain of QDs and QD−based composites, focusing on their applications in sensing, targeted drug delivery, cancer therapy, etc. Some size-dependent aspects, as well as the structural, morphological composition and outstanding properties of QDs are summarized. Considering that the risk and health hazard of the QDs must be eliminated prior to human exposure, some new toxicity issues of QDs are also presented. Due to their unique properties including good biocompatibility and low cytotoxicity, QDs are of great value in diverse fields and perform a major role in the progress of research in bioimaging, cancer therapy, tissue engineering, sensors, drug delivery, etc.

12.1 Introduction

The limited availability of fossil fuels and global warming are demanding the use of renewable energy. The potential of solar energy as an alternative for fossil fuels has been investigated over the past half century and its reliability along with marketability is understood thoroughly. The 4.3×10^{20} J h^{-1} of energy known to reach Earth from the Sun is sufficient to accomplish the annual energy consumption of Earth, 4.1×10^{20} J (Lewis and Crabtree, 2005). Highly efficient and low-cost solar cells were introduced to collect solar energy. Here, the photovoltaic cells (PVs) convert the solar energy into electrical and chemical energies (Kazacos et al., 1980). The first kind of solar cells were of p-n junction technology and Schottky barrier, which adopt the PV characteristics of appropriate semiconductor (Badawy et al., 1990). The best example is Si (Badawy and El-Dessouki, 1985; Decker et al., 1983).

Launching with Si-single crystals, and proceeding to bulk polycrystalline silica wafers, these cells are considered as first-generation cells. A 12%–16% conversion efficiency has been achieved for these cells and these are marketed widely, where the principle of energy storage is lead-acid batteries (Sharma et al., 2015). The second-generation solar cells evolved with the science of thin films. Si-wafers, CdTe, a-Si, $CuInSe_2$, and CdS are the key candidates for thin-film solar cells. In comparison with the first-generation solar cells, these thin-film solar cells presented a cost-efficient engineering process in association with integrated lower temperature progressions for the insulation of cells. Besides the use of flexible substrates helped to spread their

Quantum Dots. DOI: https://doi.org/10.1016/B978-0-12-824153-0.00012-4

accessibility for a wide spectra of applications. A conversion efficiency of nearly 20% was achieved for combination PVs such as CIGS (Cu/In/Ga/Se) (Schock and Noufi, 2000; Wada et al., 2001; Kaelin et al., 2004). However, due to the lesser stability, the thin-film solar cells shared a lower market and the efforts of researchers into improved versions of PVs were anticipated. A combination of polymers and semiconductors came into existence, where polymers were doped to form Schottky barriers (Amani-Ghadim et al., 2022; Gamboa et al., 1998). Nonetheless, the lower conversion efficiency restricted their practice.

An association of nanoscience, nanotechnology, and surface science resulted in sustainable energy conversions and consideration for third generation solar cells. Nanocrystals and nanoporous materials are employed to increase the efficiency as well as stability of solar cells. Attention to catalysts and light harvesting materials such as TiO_2, quantum dots, and many other nanocomposites has been increased to work on the nanostructured solar cells to bring out the breakthrough potentials. This chapter deals with the exercise on fabrication and advancements in one of such nanostructured materials, QDs involved solar cells.

QDs are the semiconductor clusters of nanoscale and are known for their extraordinary optoelectronic properties. The size-dependent quantum physical features of QDs present tunable optoelectronic properties attributed to the production of electron−hole pairs, which extend their use in solar cells. The cells also offer a tunable bandgap to match with the wavelength of illuminating light to generate more electricity (Badawy, 1993). QDs pose a simple method of synthesis and are economically feasible. The remarkable excitation coefficients and wide adsorption spectra depending on their size are attractive features for PV applications. The carrier multiplication phenomenon in QDs demonstrating the generation of more than one electron for an adsorption of one electron at broader wavelength spectra results in higher quantum efficiencies of QDs sensitized solar cells (QDSSCs) (Nozik, 2002; Sambur et al., 2010). This phenomenon is known as multiple exciton generation (MEG).

12.1.1 Basic structure of quantum dot sensitized solar cells

An elementary structure of QDSSCs is given in Fig. 12.1.

The key structure involves four major portions:

- photoanode;
- sensitizer, which is QD;
- electrolyte; and
- counter electrode (CE).

A photoanode is generally a semiconducting material deposited on transparent substrate and is usually a fluorine-doped tin oxide (FTO) and or

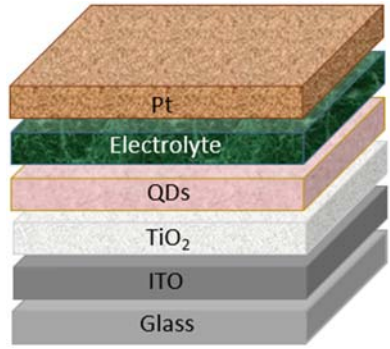

FIGURE 12.1 Primary structure of QDSSCs. *QDSSCs*, QD-sensitized solar cells.

indium tin oxide (ITO). FTO usually maintains the semiconducting layer and employs current collection. An ideal FTO should have higher transparency and lower electrical resistance, which allows the maximum transmittance of sunlight to facilitate an efficient charge transfer phenomena (Shin et al., 2019). The importance of a photoanode in QDSSCs is attributed to the contribution of a matrix for adsorption of QDs and it also acts as a charge transport medium, which could transport electrons from the sensitizer to the conducting oxide substrate. Photoanodes must have higher electron mobility and surface area and must not react with redox electrolytes. These ideal characteristics allow the maximum loading of QDs and reduce unwanted photon adsorption. TiO2 is considered as the best material as a photoanode due to its wider and tunable bandgap, low cost, stability, and nontoxicity, as well as its mesoporous features, higher surface area, conduction band edge, and greater electron affinity (Ahmad et al., 2017).

The second portion is a sensitizer. In QDSSCs it is QDs. QDs such as InP (Crisp et al., 2018), CdS (Vázquez et al., 2016), CdSe (Lee and Lo, 2009), Si (Hao et al., 2009), PbS (Park et al., 2019), PbSe (Zhang et al., 2014), CdTe (Badawi et al., 2013), graphene (Guo et al., 2010), $CuInS_2$ (Li et al., 2012), Bi_2S_3 (Zumeta-Dube et al., 2014), and many others have been used in QDSSCs. The QDs, which are stable upon visible light irradiation, with high adsorption efficiency and suitable bandgap energy, are the most preferred ones. These QDs are fabricated to act as sensitizers by two different methods. The first one is a successive ionic layer adsorption reaction (SILAR) method, and it is an example for in situ fabrication (Yang et al., 2015a,b). The other is a linker-assisted assembly method and it is an example for ex situ fabrication (Li and Zhong, 2015). However, in situ methods have shown improved performance (Bhambhani, 2018).

The third major part is a redox electrolyte, which transfers the charges between photoanodes and CEs and aids the restoration of oxidized QDs (Wu et al., 2015). These are also called hole conductors. As Cd chalcogenides

QDs are not stable in an iodide/triiodide electrolyte system, this system is most commonly practiced with an addition of suitable organic solvents (Yella et al., 2011). Several efforts have been tried out to stabilize the polysulfide electrolyte systems to avoid the leaching of QDs and the protective films have been coated (Shalom et al., 2009). Yet, the overall performance of the cell remained insignificant with just 3% of power conversion efficiency. However, polysulfide redox system (S_2/Sn^{2-}) is used instead with greater challenges like high redox potential (Hod and Zaban, 2014). To overcome this challenge, scientist have tried to control the concentration of polysulfide (Liao et al., 2015), varied solvent systems (Li et al., 2011), coupling with additives such as poly(vinyl pyrrolidone) (PVP) (Jiang et al., 2016), SiO_2 (Wei et al., 2016a), guanidine thiocyanate (Chou et al., 2011), etc. The research has been also concentrated on using a material that possesses lower redox potential like Mn poly(pyrazolyl) borate (Haring et al., 2014). Besides, the toxicity of liquid electrolytes vapor is another challenge, which arises due to leakage of solvents due to their lower boiling points. This aids to degradation of solvents and reduces the durability of the solar system. Hence solid-state electrolytes and/or quasisolid-state electrolytes are used as a substitute for liquid ones (Yu et al., 2010; Huo et al., 2015; Feng et al., 2016). Poly(ethylene oxide)/poly(vinylidene fluoride) (Yang and Wang, 2015), PVP (Jiang et al., 2016), and P3HT (poly-3-hexylthiophene) (Shaw et al., 2008) are the accomplished solid electrolytes. Some hydrogels (Zhang et al., 2017), ionic liquids (Jovanovski et al., 2011), and gels (Kim et al., 2014) are used as quasisolid-state electrolytes.

The last major portion is the CE, which allows the movement of electrons from therexternal circuit to electrolytes and also acts as a catalyst in reducing the oxidized electrolyte. The reduction reaction takes place at the interface of electrolyte and CE. For an ideal CE, the material must be highly electrical conductive with great electrocatalytic activity and also stability. Platinum is the widely used CE for QDSSCs with an electrolyte system of iodide/triiodide. But for a polysulfide system, the conversion efficiency decreased as the sulfur atoms are likely to adsorb on Pt. To overcome this, metal chalcogenides (Meng et al., 2015), many composite materials (Yang et al., 2012; Gopi et al., 2018), and also carbon-based materials (Zhang et al., 2010; Du et al., 2016) are emerging as new CEs for QDSSCs.

12.1.2 Working principle of quantum dot sensitized solar cells

QDSSCs work in a similar fashion to DSSCs. The schematic representation of the working principle of QDSSC is provided in Fig. 12.2. The photoexcitation of the sensitizer takes place with an irradiation of light. The excited electrons from QDs are transferred to the TiO_2 conduction band. These injected electrons breach through the TiO_2 nanocrystal film and reach the conducting substrate. These electrons then flow through the external circuit

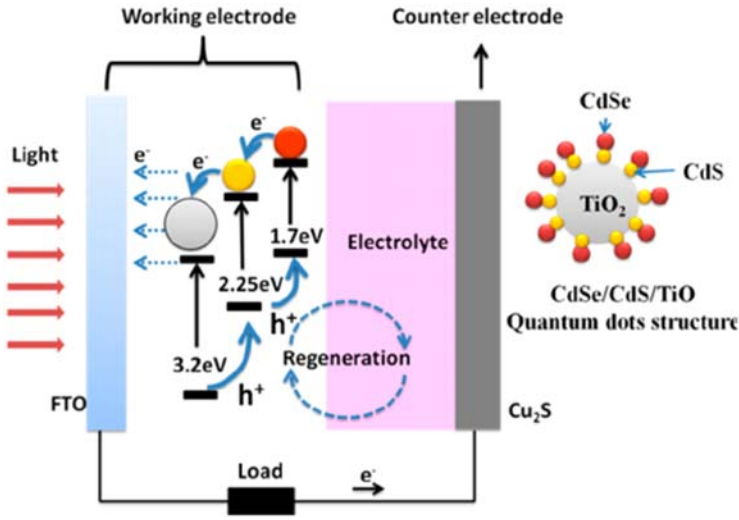

FIGURE 12.2 Working principle of QDSSCs. *QDSSCs*, QD-sensitized solar cells (Tian et al., 2012). *Adapted from Tian, J., Gao, R., Zhang, Q., Zhang, S., Li, Y., Lan, J., et al., 2012. and reach the CE. Proceeding further, the reduction of oxidized compound of the electrolyte takes place at CE and hence the regeneration of sensitizer, that is, QDs are there for the continuing process.

12.2 Properties of quantum dots

12.2.1 Energy gap tuning

The bandgap of QDs plays a major role in QDSSCs, because an appropriate bandgap can enhance/control the photon absorption in the solar spectrum. QDs possess tunable bandgap energy, which can be tuned by varying the size of QDs because of the quantum confinement effect, which occurs in the particles having a smaller size than the exciton. QDs solution displays a different color that corresponds to the change in the particle size, which exhibits a different absorption band of light. This effect increases the bandgap along with a blueshift in photoluminescence (PL). Therefore, the selection of an appropriate absorber for designing an efficient solar cell is very important. Anttu (2015) have found that the balance limit for photon conversion efficiency in a single junction solar cell depends strongly on the bandgap of absorbing material. Literature reports that the driving force of 0.25 eV is sufficient for the electron injection into photoanode (Weller, 1991). Therefore for better electron transport, the conduction band (CB) of QDs absorber

should be 0.25 eV above the CB of the photoanode for efficient exciton dissociation and the valence band level of QDs should be lower than the redox level of the hole transporting material.

A decrease in size of CdSe QDs increases the bandgap (Fig. 12.3) and hence the emission of PL shifts from red to blue. A decrease in particle size of CdSe increases the photocurrent, attributed to the shift of the CB towards a more negative potential, which enhances the driving force for charge injection. However, the higher particle size materials shows better absorption in the visible region but the disadvantage of these materials is lower electron injection into TiO_2, unlike with small-sized QDs. Vogel et al. (1994) reported that the charge separation can be optimized through tuning the size of QDs and Kongkanand et al. (2008) demonstrated that the photoelectrochemical response and photoconversion efficiency (PCE) can be enhanced by varying the size of QDs.

The sufficiently small QD particles represent wider bandgap energy; consequently, the optical absorption and emission with regard to excitation across the bandgap shift to higher energy. Gorer and Hodes (1994) have investigated the quantum size effect in CdSe films and observed blueshift of the absorption spectra with the decrease in crystal size. This phenomenon is also reported in CdS QDs by Thambidurai et al. (2011). Jun et al. (2013) have suggested that the use of a combination of different sizes of QDs having a range of bandgaps in a solar cell may show better efficiency due to a

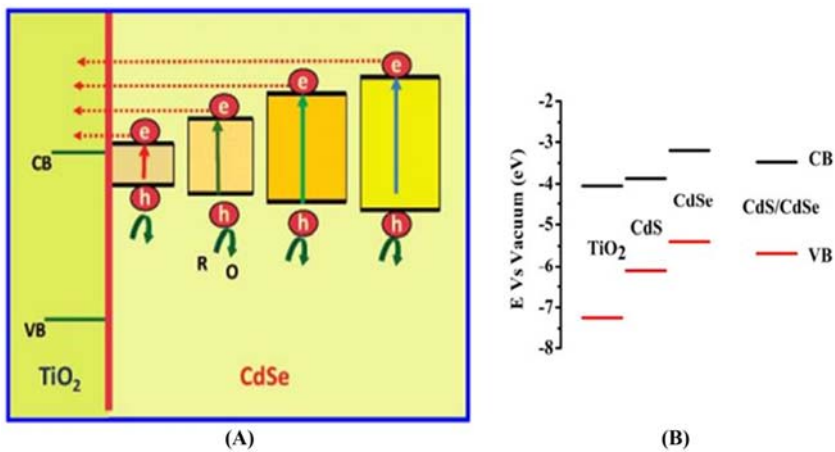

FIGURE 12.3 (A) Schematic illustration of energy band structure of different sized CdSe QDs and TiO_2. (B) Band energy of TiO_2, CdS, CdSe and co**sensitized** CdS/CdSe. *Adapted from Kongkanand, A., Tvrdy, K., Takechi, K., Kuno, M., Kamat, P. V., 2008. Quantum dot solar cells. Tuning photoresponse through size and shape control of CdSe − TiO_2 architecture. J. Am. Chem. Soc. 130 (12), 4007–4015; (B) Esparza, D., Zarazúa, I., López-Luke, T., Cerdán-Pasarán, A., Sánchez-Solís, A., Torres-Castro, A., et al., 2015. With permission.*

wider absorption of light. Esparza et al. (2015) have sensitized two different QDs with a varied range of light absorption on TiO_2 and demonstrated that the PCE for CdS/CdSe (PCE = 4.7%) is higher than CdS alone (PCE = 2.5%), which are prepared by SILAR (CdS), electrophoretic deposition (CdSe), and pipetting (CdSe) methods, respectively. The use of different kinds of QDs sensitizers is a promising technique to enhance the light absorption wavelength region, increase electron injection, and also enhance the charge transport, which improves the photon conversion efficiency.

12.2.2 Multiple exciton generation

The effectual formation of more than one photoinduced electron−hole (e^-−h^+) pair upon absorption of a single photon is potentially important for the development of optoelectronic devices (photovoltaic and photoelectrochemical cells), which convert solar radiation (energy) into electricity. In some cases, stored chemical potential is there in solar-derived fuels like hydrogen, alcohols, and hydrocarbons. Several workers explain the dynamics of such a conversion process (Hanna and Nozik, 2006; Klimov, 2006). The conversion process increases because of the excess kinetic energy of the electrons and holes that are produced by the absorption of photons in a cell, with the energies above the bandgap energy for absorption, and can create additional e^- /h^+ pairs with at least the twice the bandgap energy (Nozik, 2008). The additional e^- /h^+ pair is created by the bandgap in a semiconductor and HOMO−LUMO energy difference in molecular systems. These extra e^- /h^+ pair can be separated, transported, and collected to yield higher photocurrent in the cells. In such a process, the excess kinetic energy is converted to heat and can become unavailable for conversion into electrical free energy, thus limiting the cell to achieve the maximum thermodynamic conversion efficiency. The hot carrier and relaxation of electrons in semiconductor is shown in Fig. 12.4. The creation of the (e^- - h^+) pair, which absorbs the proton, has been studied for over 50 years in bulk semiconductors. It has also been observed in photocurrent of bulk p-n junctions in Si, PbS, PbSe, PbTe, and InSb, and in these systems, they are termed as impact ionization (Tauc, 1959; Vavilov, 1959; Beattie, 1962; Christensen, 1976; Kolodinski et al., 1993). Nevertheless, the impact of ionization is not an effective process in bulk semiconductors and may require more multiples of photoenergy for threshold absorption of energy. For an Si-based semiconductor PV, which is dominant in the present-day photovoltaic market, impact ionization does not become significant until the incident photons energy exceeds 3.5 eV. This energy is an ultraviolet energy threshold, which is beyond the photon energies present in the solar spectrum. Even with absorption of 5 eV photons, impact ionization only generates a quantum yield (QY) of 1.3. Hence it is not a meaningful approach to increase the efficiency of conventional bulk Si PV with impact ionization.

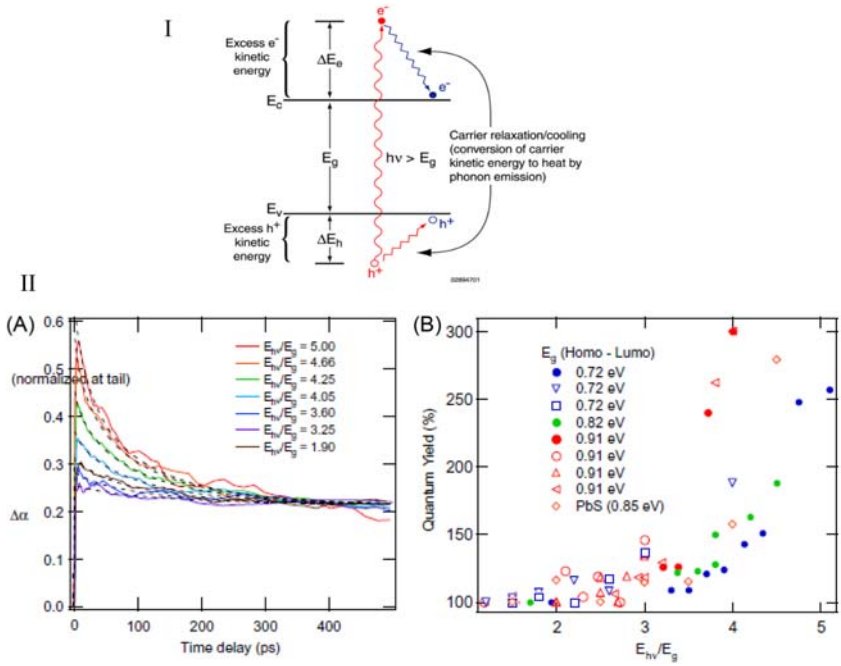

FIGURE 12.4 (I) Hot carrier relaxation/cooling in semiconductors. (II) (A) Exciton population decay dynamics obtained by probing intraband (intraexciton) transitions in the mid-IR at 5.0 μm for a sample of 5.7 nm diameter PbSe QDs, and (B) QY for exciton formation from a single photon versus photon energy expressed as the ratio of the photon energy to the QD bandgap (HOMO−LUMO energy) for three PbSe QD sizes and one PbS (dia. = 3.9, 4.7, 5.4, and 5.5 nm, respectively, and Eg = 0.91, 0.82, 0.73, and 0.85 eV, respectively). Solid symbols indicate data acquired using mid-infrared probe; open symbols indicate band edge probe energy. Quantum yield results were independent of the probe energy utilized (Beard et al., 2015). *Adapted (I) from Beard, M. C., Johnson, J. C., Luther, J. M., Nozik, A. J., 2015. Multiple exciton generation in quantum dots vs singlet fission in molecular chromophores for solar photon conversion. Phil. Trans. R. Soc. A: Maths, Phys. Eng. Sci. 373 (2044), doi: 10.1098/rsta.2014.0412.; (II) Ellingson, R. J., Beard, M. C., Johnson, J. C., Yu, P., Micic, O. I., Nozik, A. J., et al., 2005. Highly efficient multiple exciton generation in colloidal PbSe and PbS quantum dots. Nano Lett. 5 (5), 865−871. With permission.*

On the other side, the semiconductor nanocrystals (QDs) generating the multiple (e^- /h^+) pairs from a single photon are more efficient. The threshold photons required to generate become more efficient and such photon energy for the same process generates two (e^- /h^+) pairs per photon absorbed, which can approach values as low as twice the threshold energy for the absorption. In QDs, the rate of Auger recombination including the inverse Auger process of MEG can be increased. The enhancement is due to the carrier confinement and this correspondingly increases the (e^- /h^+) coulomb interaction with a time scale reported to be more than 100 fs (Ellingson

et al., 2005; Shabaev et al., 2006). The rate of velocity of generation of MEG is much faster than the hot exciton cooling rate produced during the process of recombination and thus MEG can be become more efficient. However, Nozik (2001) noted that crystal momentum is not a good quantum number and momentum need not to be conserved. This allows the threshold photon energy to generate two (e^- /h^+) pairs per photon absorbed. Lowering the threshold to absorb more photons would lower the kinetic energy lost due to heat and reflection. This allows the solar spectrum to contribute more photons with a particular ideal or particular bandgap of the material, which could possibly enhance the MEG.

MEG has been detected by several spectroscopic techniques and is consistent (Schaller and Klimov, 2004; Ellingson et al., 2005; Schaller et al., 2005). The first method is by using transient absorption spectroscopy, which measures with respect to time (can measure from femto to microsecond transition). It can measure the data from delays as low as 5 ps, by which in some material, the carrier multiplication and cooling are complete and probe pulse is catechizing the exciton population at their lowest possible state (band edges) (Schaller et al., 2006). It also monitors the interband bleach dynamics with excitation across the QD bandgap. In the other set of experiments, probe pulse is in mid-IR and monitors the interband transitions of the new excitons that are created. The peak magnitude of the initial time induced photon absorption change is created by the pump pulse and the Auger decay dynamics of the generated excitons and it is equal to the number of excitons generated. The dynamics of the mid IR interband absorptions are monitored after the pump pulse. Fig. 12.4B gives the excitation decay probing interband transition of PbSe QDs.

The exciton multiplication was first reported and presented by Schaller and Klimov (2004) for PbSe QDs. They showed that an excitation energy threshold for the efficient formation of two excitons per photon at 3 Eg, where Eg is the absorption energy gap of the QDs (HOMO-LUMO transition energy) commonly called bandgap in QDs. They also reported that the QY of 218% (118% Impact Ionization (I.I.) efficiency) at 3.8 Eg, and value of QYs above 200% indicates the formation of more than two excitons per photon absorbed. The research group from NREL (Ellingson et al., 2005) reported QY of 300% for 3.9 nm QDs at a photon energy of 4 Eg. This indicated that there is formation of three excitons per photon absorbed for every photoexcited QDs in the sample. They have also shown that the threshold Eg of MEG by optical excitation is 2 Eg. It was also revealed that efficient MEG occurs in PbS (Ellingson et al., 2005) and PbTe QDs (Murphy et al., 2006). MEG is also seen in other types QDs such as CdS, CdSe, CdTe, ZnS, ZnSe, CdSe/CdS, CdSe/CdTe, and CdTe/ZnS but it is not limited to these only. These core−shell type of QDs mentioned not only gives the stability to the core but also stabilizes the generation of MEG.

12.3 Synthesis of quantum dots

12.3.1 Chalcogenide quantum dots

The synthesis of QDs took a rapid phase of development from its discovery by Alexy Emikov (Ekimov and Onushchenko, 1981) in a glass matrix. It took almost a decade to synthesize these in a stable colloidal form by Murray et al. (1993). There are mainly two ways to synthesize the QDs and these are: (1) solution phase synthesis (colloidal route) and (2) vapor phase synthesis. The solution phase synthesis involves the hot injection method, where the precursor is injected into the hot solution of another precursor. This development in technique led to improved QD photophysical properties such as quantum confinement, reproducibility, and size-tunable PL. The main advantage of the colloidal method is that it uses injection and growth temperature to control the QD particle size. It is well known that nucleation and growth of the QDs depends on the time and temperature of the colloidal precursor solution, which can be controlled (Chandan and Geetha, 2013; Chandan et al., 2014). This led to the development of QDs such as CdSe, CdS, CdTe, ZnSe, and ZnS. This enhancement of photophysical properties with stability of QDs marked their presence and importance in photovoltaics, energy, biosensors, and bioimaging (D'Souza et al., 2015; Venkataramana et al., 2016; Kusuma et al., 2019; Ravikumar et al., 2019, 2020). Apart from these QDs, near infrared emitting QDs are InP, InAs, and other lead and copper chalcogenides (Micic et al., 1994, 1995; Allen and Bawendi, 2008; Tan et al., 2017).

The stable CdSe colloidal QDs were first synthesized and reported by Murray et al. (1993). They were the first to report the use of TOPO/TOP (Trioctyl phosphine oxide/Trioctyl phosphine) as a coordinating and stabilizing agent. They were successfully able to synthesize group II−VI QDs with PL. But this technique was plagued by Ostwald's ripening. To overcome this, Katari et al. (1994) replaced TOP with tributylphosphine, which allowed spontaneous nucleation with a relatively slow rate of growth; incidentally increasing the stability of the QDs with TOPO as capping agent. $CdMe_2$ was used previously as the precursor for the synthesis of QDs and needed to be replaced due to their pyrophoric and toxic nature. Peng and Peng (2001) solved this problem with use of less toxic CdO (cadmium oxide) along with a long-chain fatty acid, oleic acid. This reduced the use of the toxic phosphine derivative, paving the way for much greener solvents for the synthesis. Chandan et al. (2014) reported the use of more environment-friendly ligands such as oleic acid and octadecyl amine as growth and nucleating ligands for CdSe synthesis. They investigated the effect of these ligands on the nucleation and growth of CdSe QDs and found these were stable over months. Such QDs with increased stability are better suited for photovoltaic application, keeping in the mind that it has to be exposed to an outdoor

environment. QDs were also synthesized in an aqueous solution of respective salts. Even though, there are several research reports on such synthesis, they lack stability and better confinement is not possible due to an elongated reaction time. Some reactions can be as long as 6 days, which can lead to polydispersed QDs.

Electron−hole pair recombination and leaching is the main concern in QDs, which affects the performance and stability of the device. This can be mitigated by forming the shell structure or inserting the dopant on the surface of the core QDs structure. Such an introduction can reduce recombination and increase the stability. Thus plain core QDs (CdSe, CdS, ZnS and CdTe) have countered comparatively less attention than core−shell structures such as CdSe/CdS, CdSe/ZnS, CdTe/CdS, etc. but it is not limited to these only. The thickness of the shell can be monitored and controlled by varying the same ligand used by monitoring the injection time, concentration of the shell precursor, and capping material used (Zhu et al., 2010a,b). CdSe/CdZnS QDs were reported by Schrier et al. (2012) and the maximum QY was 100%, which is the highest reported QY for the chalcogenide series of QDs. If the shell coating on the core is smaller, then it can lead to complete transmittance of electromagnetic radiation (light) through the shell to reach the core. Such a process can increase the QY of the material and reduce the electron−hole pair recombination. Another strategy to increase the PL QY is to incorporate the dopant into the energy level of the QDs. Dopants such as Mn, Cu and Ag can significantly increase PL QY over 50% (Chen et al., 2009). Doped QDs can emit significantly in the visible region with large Stokes shifts and decay time ranging from micro- to milliseconds timescales (Wood et al., 2009). Fig. 12.5 shows the schematic representation of surface passivation and related surface chemistry.

Vapor phase synthesis of QDs is a rather less known technique than the hot injection method due to its complexity. It can be formed via deposition from vapor onto the appropriate substrates in molecular beam epitaxy (MBE) or metal organic chemical vapor deposition. There are two approaches to form the QDs. The first is Stranski−Krastinov (SK) growth, where nanosized islands are formed with several monolayers deposited upon one another. This leads to the large lattice mismatch between the two semiconductor materials. This was observed in Ge/Si, InP/AlGaAs, and InP/GaInP. For such highly strained system, growth initiates with the addition of layer by layer and thus minimizes the strain energy. Such islands then grow articulately on the substrate without any misfit until a critical strain density with corresponding to its critical size is exceeded. Incidentally, coherent SK islands can be overgrown with a suitable passivating and carrier confining epitaxial layer to produce QDs with better PL efficiency—typically colloidal QDs—which depend on the capping layer. The second method is to produce the near surface quantum well (QW) and then deposit coherent SK islands on to those wells. Such deposition has a large lattice mismatch with the barrier to

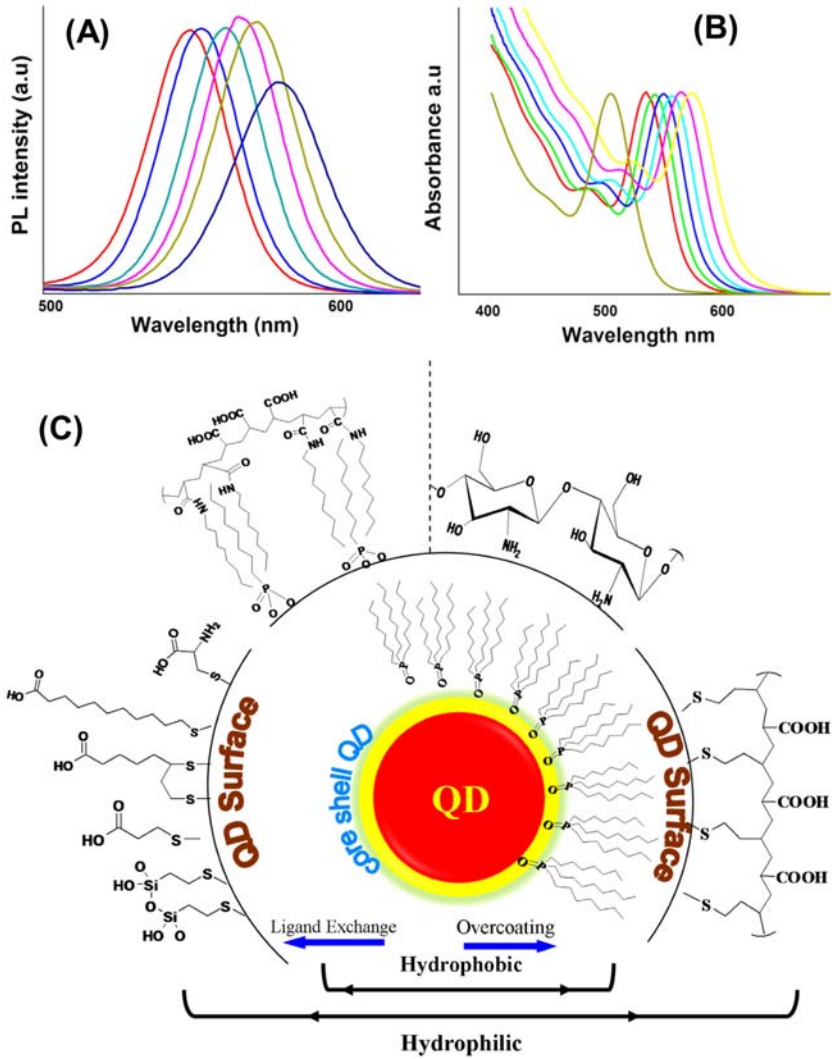

FIGURE 12.5 (A) PL; (B) UV−visible spectra of CdTe QDs; and (C) possible schemes for surface modification of QDs using ligand exchange and polymer coatings (Chandan et al., 2018). *Adapted from Chandan, H. R., Schiffman, J. D., Balakrishna, R. G., 2018. Quantum dots as fluorescent probes: synthesis, surface chemistry, energy transfer mechanisms, and applications. Sens. Actuator, B 258, 1191−1214. With permission.*

produce strain in the island formed. The strain created by the island can be extended to the QW and thus it can penetrate through its outer barrier and well region. Such a strain field can expand the lattice of the QW and lowers the bandgap below the SK island formed and thus produces the quantum

dots by confining its electrons three dimensionally. Such SK islands are referred to as stress islands. Stress-induced InGaAs and GaAs have been reported for InP stress islands on GaAs/InGaAs/GaAs QW and for InP stressor islands on an AlGaAs/GaAs/AlGaAs QW (Petroff and DenBaars, 1994; Willardson et al., 1999).

12.3.2 Perovskite quantum dots

Hybrid organic−inorganic perovskite quantum dots is the new entry to the QDs family with enhanced fluorescence intensity and QY. The metal halide perovskite has the simple ABX_3 structure. "A" is occupied by organic or inorganic materials such CH_3NH_3 (MA), $CH(NH_2)$ (FA), or Cs^+. "B" by a divalent metal cation such as lead, strontium, and germanium. "X" usually is halide ions. The octahedral BX_6 structure is the basis of the perovskite and "A" is occupied by the cation, which fills the voids between these structures. Synthesis of such a structure can be also achieved through the hot injection method. During the initial stage of the development, organic−inorganic halide perovskite, such as methyl ammonium lead halide ($MAPbI_3$) and formammonium lead halide ($FAPbI_3$), gained more attention (Choi et al., 2017; Lee et al., 2019). However, these PQDs are less stable due to the organic content and soon the focus was shifted toward inorganic halide perovskites (Xiang and Tress, 2019). But the toxicity of the lead limited their use in practical applications. Until recently, most of the studies shifted their focus from $CsPbX_3$ to lead-free structures (Han et al., 2019). Hot injection method is the most common method used for the synthesis of the PQDs, with OA and ODE being the predominant ligand system for the synthesis of the PQDs (Zhang et al., 2015; Sun et al., 2018). The temperature was adjusted ranging from 150 to 200°C depending on the type of the material. Typically, the Cs oleate precursor was injected into the degassed PX_3 (X = Cl, Br, I) solution. This hot injection leads to nucleation and growth of the particle. The reaction is arrested by reducing the reaction temperature using ice cold water (immersing the round bottom flask). The synthesis of lead-free perovskite gained more interest.

Zhou et al. (2018) demonstrated the synthesis of $Cs_2AgBiBr_6$ perovskite QDs. Typically, the Cs-oleate was injected into the mixture of $BiBr_3$, $AgNO_3$, ODE, OA, and HBr at 200°C under inert condition or N_2 atmosphere. This led to the formation of $Cs_2AgBiBr_6$ PQDs with a time span of 5 s. In fact, the morphology of the PQDs synthesized by hot injection method is monitored by three factors influencing it (Wang et al., 2016; Dolzhnikov et al., 2017; Zhou et al., 2018; Xu et al., 2019). This includes the reaction time of the two precursors, the temperature and the ratio of the ligands. Wang et al. (2015) reported the synthesis of Cs_2SnI_6 PQDs. They demonstrated that reaction time is very important in the hot injection method. Usually the reaction is short with less than a minute, and it results in cubic

structured PQDs. However, when the reaction time is progressed, a different morphology of the PQDs was formed. The formation of nanorods, nanowires, nanobelts, and nanoplatelets was reported with a time scan of 5, 10, 30, and 60 min, respectively (Zhou et al., 2018). Similarly, the effect on the morphology of PQDs by variation of temperature and ligand ration was also reported by Dolzhnikov et al. (2017) and Xu et al. (2019), respectively. Fig. 12.6 gives schematic presentation for hot injection method and effect of reaction time over morphology.

Another method of synthesizing PQDs is ligand-assisted synthesis. To solve some of the challenges associated with the hot injection method (high reaction temperature and low reproducibility for large-scale synthesis), this method came to existence. It is a simple synthetic process, which involves the principle of supersaturation in the presence of ligands. PQDs were synthesized by dropwise addition of precursor solution in polar solvent into a solvent containing ligands. The difference in the polarity of the solvent system influences the miscibility of solvents. Thus it resulted in two solvent systems, which cannot mix, and the precursor present encounters a nonequilibrium state. Due to this supersaturation, nucleation and growth occurs immediately even at room temperature and the product can be produced at gram scale with reproducibility.

Gram-scale synthesis of lead-based PQDs was reported using this method (Liang et al., 2016; Wei et al., 2016b). Yang et al. (2017) reported the synthesis of $Cs_3Bi_2Br_9$ PQDs by a one-step reaction without ligands. CsBr and $BiBr_3$ were dissolved in dimethylsulfoxide (DMSO) to form a precursor solution. As DMSO is a polar solvent, therefore when such a precursor solution was added to the less polar solvent such as isopropanol (which can act as antisolvent), a yellow-green colloidal solution was formed. This indicates the nucleation and growth of $Cs_3Bi_2Br_9$ PQDs formation even without the presence of ligands. Nevertheless, the low QY of 0.2% indicates the requirement of ligands.

Leng et al. (2018), synthesized $Cs_3Bi_2Br_9$ by this method using OA and oleylamine (OLA) as ligands. This protocol for the synthesis is similar to Yang et al. (2017) except for two reaction conditions. The first one is that actone was used as the antisolvent and second is that precursor solution was prepared using OLA and antisolvent OA. It resulted in PQDs $Cs_3Bi_2Br_9$ having an average diameter of 3.88 nm and QY of 19.4%. Even though the ligand-assisted method is advantageous in terms of reaction temperature, there are some issues that need to be addressed. Typical to chalcogenide QDs synthesis using hot injection method, the nucleation occurs at early stage of the reaction, which is followed by the growth. This allows one to arrest the reaction depending on time or temperature. But in ligand-assisted synthesis, the nucleation and growth stages cannot be separated, indicating the difficulties in controlling the size and morphology of the PQDs (Lignos et al., 2016). Another problem associated with halide PQDs is that the polar solvents are used in ligand-assisted reaction. The halide PQDs are vulnerable to the polar solvents with the possibility that PQDs may undergo degradation or aggregation losing their properties. Other than this method, one-step synthesis using an ultrasonication method has also been reported, where all the precursors have been dissolved in appropriate solvent and sonicated. The PQDs can be synthesized with the use of the same ligand system (Tong et al., 2016; Jang et al., 2016). Nevertheless, there is always scope to improve the synthetic route for better quality products.

12.4 Quantum dot sensitized solar cells

Several QDs are used in QDSSCs as sensitizers, which include $CsPbX_3$, CdS, CdSe, CdTe, ZnS, Ag_2Se, PbSeS, $AgInSe_2$, PbS, $CuInS_2$, and $MAPbX_3$ (Lin et al., 2020). Among all these QDs sensitizers, CdS and CdSe QDs are considered significant choice as stable materials in QDSSCs. The enhancement in PCE observed in QDSSCs are mainly contributed by the increase in size of QD, enhanced light harvesting, reduced defects, improved charge carrier migration and higher surface area covered by the QDs on the photoelectrode. Lee and Lo (2009) have used CdS/CdSe cosensitized photoelectrode for QDSSC application and reported that CdS and CdSe QDs exhibits complementary effect in light harvesting due to stepwise arrangement of band edge levels, which is beneficial for the injection of electron and recovery of hole between CdS and CdSe (Fig. 12.7) resulting in a PCE of 4.22% using a TiO_2/CdS/CdSe/ZnS electrode. Introduction of ZnS layer acted as a passivation layer to protect QD materials from photocorrosion and improves the photovoltaic effect of QDSSCs.

Archana et al. (2020) have studied the cosensitization effect of CdS and InSb QDs and reported an improved PCE for TiO_2/CdS/InSb QDSSC that is 0.8% (InSb) and 3.52% (CdS QDs) to 4.94% (InSb QDs and CdS QDs). The cosensitization of InSb improves the light absorption range along with reduced spectral overlap leading to better light harvesting and decreased defects causing suppressed recombination of charge carriers. Liu et al. (2019) have used zinc titanium mixed metal oxides as photoanodes with CdS/CdSe QDs for QDSSCs and reported PCE of 3.95%. Yu et al. (2012) have prepared CdSe/CdS core/shell nanocrystals and showed an improved Jsc, Voc, and η compared to single CdSe QDSSCs, due to higher light

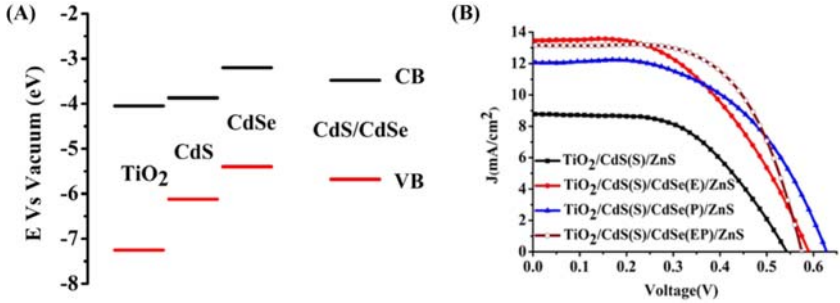

FIGURE 12.7 (A–B) Band edge structure for TiO_2, CdS and CdSe electrodes and (C) I–V curves for QDs sensitized solar cells. *Adapted from Esparza, D., Zarazúa, I., López-Luke, T., Cerdán-Pasarán, A., Sánchez-Solís, A., Torres-Castro, A., et al., 2015. Effect of different sensitization technique on the photoconversion efficiency of CdS quantum dot and CdSe quantum rod sensitized TiO_2 solar cells. J. Phys. Chem. C. 119 (24), 13394–13403. With permission.*

harvesting ability. In addition, CdSe/CdS prevents recombination of charges inside QDs by decreasing surface states and by accelerating charge separation, suggesting that cosensitized QDs are better than single QDs. Another approach to improve QDSSCs performance is by incorporating passivation layer like ZnS between TiO_2 (photoanode) and electrolyte in CdS QDs solar cell. The decreased recombination of charge carriers from TiO_2 to electrolyte was observed in the presence of passivation layer, leading to enhanced charge collection efficiency (Jung et al., 2012).

Li et al. (2020) have introduced TiO_2 as a passivation layer between ZnO hollow microspheres photoanode and CdS/CdSe/ZnS, which showed an improved PCE of 3.16% as compared to bare ZnO of 1.54%. This enhancement was attributed to improved light absorption and electron transport resulting from TiO_2 incorporation. Yu et al. (2012) studied effect of different annealing temperatures (100°C, 150°C, 200°C and 250°C). QDSSC performance in CdSe/CdS QDs, exhibited an increased IPCE from 0.46% to 2.83%. A significant enhancement in efficiency of 4.21% was observed with 300°C annealing temperature as compared to the photoanode, which was not treated with heat, which exhibited only 3.2%. In addition, CE and electrolyte can also be modified to enhance the properties of QDSSC. CoS (Yang et al., 2010) and Cu_2S are used as CE in ZnS/CdSe/CdS multilayer QDSSCs and they showed an increased efficiency of 2.7% and 1.9%, respectively in comparison to Pt CE with an efficiency of 1.6%. Furthermore, recently Cu_2S and rGO composites have open up new path for CE material choice for QDSSCs (Kusuma et al., 2018).

Huang et al. (2011) reported a flexible photoelectrode for CdS/CdSe quantum dot-QDSSCs with a PCE of 3.47% under AM 1.5G illumination using Cu_2S CE and polysulfide electrolyte between the electrodes. The conventional flexible transparent conductive oxides substrates like ITOs−polyethylene terephthalate (ITO-PET) cannot tolerate high temperature and hence they have also investigated a new technique of depositing the TiO_2 and FTO layer first, followed by PET substrate at lower temperature in order to avoid temperature issues for CdS/CdSe QDSSCs photoelectrodes. Yu et al. (2011) have used electrodeposition method to fabricate CdS/CdSe QDs with TiO_2 as a photoanode and reported an improved electron transport and electron collection efficiency with a PCE of 4.81%.

Li et al. (2011) have used modified polysulfide $[(CH_3)_4N]_2S/[(CH_3)_4N]_2S_n$, in organic solvent (3-methoxypropionitrile) to improve the QDSSCs performance. They observed an increased PCE of 3.2% under AM 1.5G irradiation by employing CdS QDSSCs. The modified polysulfide contributes in linking QDs with nanoporous TiO_2 through covalent bonds using thioglycolic acid resulting in high wettability and superior penetration capability of TiO_2 with an improved fill factor of 0.89. Pan et al. (2012) prepared CdS/CdSe inverted type-I core/shell structure deposited on TiO_2 photoanode with a bifunctional linker mercaptopropionic acid (MPA), which showed an

improved PCE of 5.32%. It was attributed to modified deposition technique using linker MPA.

Zhu et al. (2010a,b) have used Zn-doped TiO_2 screen printed on FTO as a photoanode for CdS QDSSCs and reported an improved PCE by 24% and it was attributed to reduced electron recombination and enhanced electron transport by Zn doping. Santra and Kamat (2012) have reported that QDSSCs exhibited a significant enhancement in PCE (5.4%) on doping Mn^{2+} to CdS. Mn-doped ZnS, ZnSe and CdS depicted emission at 585 nm resulting from d-d transition, but these transitions are both; spin and orbitally forbidden, leading to a very long lifetime in the range of several hundreds of micro seconds (Fig. 12.8). Hence it is advantageous to utilize long lived charge carriers to enhance the PCE in QDSSCs using Mn-doped QDs (Santra and Kamat, 2012). Some parameters of CdQDs-based solar cells are tabulated in Table 12.1.

12.4.1 Perovskite quantum dots-based quantum dot sensitized solar cells

Organometallic halide perovskites having the formula ABX_3 (where A is an organic cation, B is commonly Pb^{2+}, and X is a halide) have inspired photovoltaics field due to their unique photophysical properties like high emission efficiencies, long carrier diffusion lengths and low production cost. It makes them as potential candidate for photovoltaics and optoelectronics applications. The research in this field is highly focused on organic−inorganic hybrid perovskites, for example, $CH_3CH_3PbI_3$, $CH_3NH_3PbI_3$, etc. and later the volatile organic part is substituted by inorganic materials such as $CsPbX_3$, X = Cl, Br, and I with cubic perovskite structure. The organic−inorganic $CH_3CH_3PbI_3$ perovskites will dissociate into PbI_2 and CH_3NH_3I under environmental stress; the latter is volatile, and therefore,

replaced with inorganic material. The first perovskite-based solar cells was reported by Kojima et al. (2009) with PCE of 3.8% using $MAPbI_3$ and $MAPbBr_3$ as a liquid sensitizer in DSSC-based structure. Im et al. (2011) have used quantum dots of nanocrystalline material and enhanced the PCE to 6.54%. The incorporation of solid hole transporting layer (HTL) spiro-OMeTAD instead of liquid HTL has boosted the PCE in recent years. Presently, perovskites cells have reached an efficiency of 25.5% to convert sunlight into electricity and perovskite silicon tandem solar cells reached PCE of 29.5% as depicted in NREL chart (Fig. 12.9), which is at par with the best thin-film chalcogenide and silicon devices.

Swarnkar et al. (2016) have prepared phase stabilized $CsPbI_3$ QDs at lower temperature for photovoltaic applications. $CsPbI_3$ undergoes immediate transformation to orthorhombic phase, when exposed to ambient conditions. The phase stabilized $CsPbI_3$ QDs stable for months at ambient conditions are developed by modifying the purification process, which includes washing with methyl acetate, an antisolvent, which eliminates

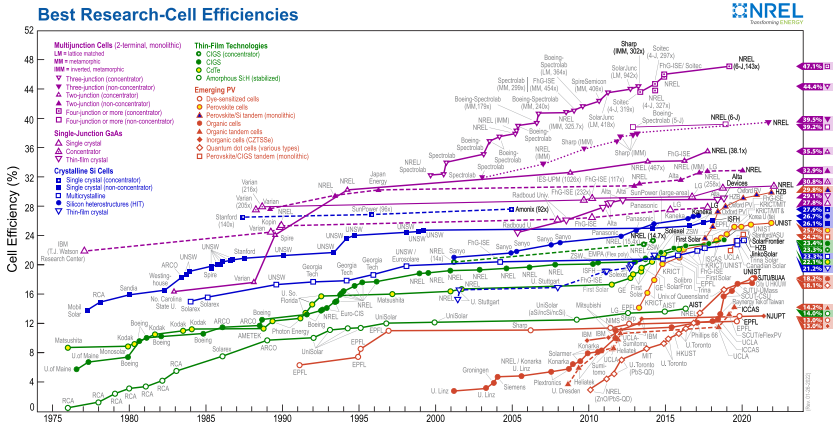

FIGURE 12.9 NREL cell efficiency chart.

unreacted precursor material without inducing agglomeration. Lee et al. (2012) have modified structure of device by replacing m- (mesoporous)-TiO_2 with insulating m-Al_2O_3, which is fabricated above the thin compact layer of TiO_2. It resulted in ten times faster charge collection with an enhanced photocurrent. Here, they concluded that mesoporous structure acts as a scaffold for perovskite structure.

Chen et al. (2017) reported that efficient vacuum deposited $CsPbI_3$ and $CsPbI_2Br$ enhances the PCE in solar cells to 11.8%. Sanehira et al. (2017) have reported that A-site cation halide salt treatment (formamidinium FA^+) enhances charge carriers mobility, resulting in increased photocurrent contributing to higher PCE of 13.43%. Here, the interaction of QDs and FA^+ might be a surface reaction or partial cation exchange resulting $Cs_xFA_{1-x}PbI_3$ QD core or a core shell structure formed by $FAPbI_3$ matrix around $CsPbI_3$ QDs, suggesting that individual QDs are no longer present. Frolova et al. (2017) have used coevaporation by thermal annealing of CsI and PbI_2 to fabricate $CsPbI_3$ perovskite solar cells, which delivered an enhanced power conversion efficiency of 10.5%. Thermal annealing contributes to phase changes in crystal structure and morphology in order to enhance the device performance by producing a well crystalline, uniform and highly pure perovskite film compared to solution-based process, where the film is affected by solvent, wetting, evaporation and deposition process (Fig. 12.10).

Lv et al. (2015) have used colloidal surface modified $CuInS_2$ QDs with improved carrier transport ability as hole transporting agent in TiO_2/$CH_3NH_3PbI_3$/HTM/Au solar cell, which showed an enhanced PCE of 8.38% along with ZnS as shell layer. The improved PCE is contributed by decreased charge recombination between TiO_2 and hole transporting material HTM. Stolterfoht et al. (2018) have visualized nonradiative recombination pathways in

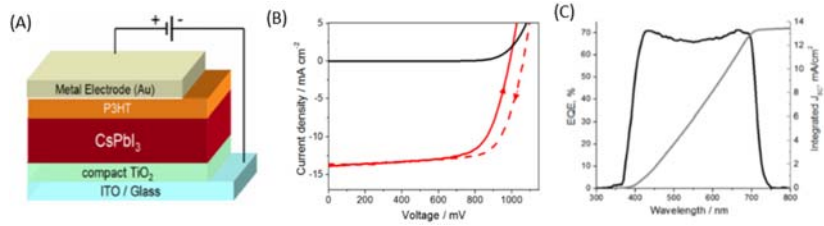

FIGURE 12.10 (A) Schematic of the PQDs solar cell, (B) current-voltage curve of device and (C) EQE spectrum. *Adapted from Frolova, L. A., Anokhin, D. V., Piryazev, A. A., Luchkin, S. Y., Dremova, N. N., Stevenson, K. J., et al., 2017. Highly efficient all-inorganic planar heterojunction perovskite solar cells produced by thermal coevaporation of CsI and PbI_2. J. Phys. Chem. Lett. 8 (1), 67−72. With permission.*

perovskite solar cells $(CsPbI_3)_{0.05}[(FAPbI_3)_{0.89}(MAPbBr_3)_{0.11}]_{0.95}$ using transient and absolute PL. They found quasi-Fermi-level splitting losses and interfacial recombination resulting in 135 and 80 meV, free energy loss. Incorporation of thin interlayers of PFN-P2—a conjugated polyelectrolyte and LiF between perovskite and transport layer contributes to a considerable decrease of these interfacial losses at both p and n contacts, by 65 and 35 meV respectively. The PCE has improved to 19.83% with a record fill factor of 81%. Zheng et al. (2020) have reported that introduction of long-chain surface anchoring alkylamine ligands into precursor solution suppressing the nonradiative recombination, which improves the optoelectronic properties of mixed-cation mixed-halide perovskite films. The resulting modified film shows (100) orientation, low trap state density in addition to improved charge carrier mobility and diffusion lengths leading to a highly enhanced efficiency of 22.3%. Some perovskite-based solar cell parameter are summarized in Table 12.2.

12.4.2 Other quantum dots-based quantum dot sensitized solar cells

QDSSCs are potential photovoltaic device systems, attributed to their low material requirements and simplicity. However, in order to achieve high efficiencies, complicated and expensive processes or toxic materials are used, which limit their large-scale application. By overcoming these limits, the QDSSCs can be used for commercial applications. Pan et al. (2014) have prepared green QDs that are free of Cd or Pb. They have applied surface passivation to the ternary $CuInS_2$ (CIS) QDs using ZnS and reported a high efficiency of 7.04% as compared to other green QDs-based QDSSCs, suggesting the possibility of better or comparable performance with green CIS QDs (Fig. 12.11). This enhanced efficiency was attributed to a high absorption range, more QDs loading, and reduced recombination with type-I core/shell structure.

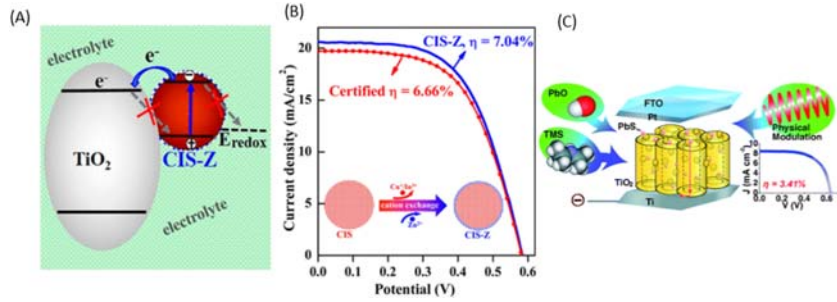

FIGURE 12.11 (A) Schematic of band structure of TiO_2 and $CuInS_2$ (CIS) QDs passivated by ZnS (B) I−V curves of CIS QDs solar cells and (C) Schematic of PbS QDs solar cell along with I−V curves. *Adapted from Tao, L., Xiong, Y., Liu, H., Shen, W. 2014. High performance PbS quantum dot sensitized solar cells via electric field assisted in situ chemical deposition on modulated TiO_2 nanotube arrays. Nanoscale. 6 (2), 931−938. With permission. Adapted from Pan, Z., Mora-Seró, I., Shen, Q., Zhang, H., Li, Y., Zhao, K., et al., 2014. High-efficiency "green" quantum dot solar cells. J. Am. Chem. Soc. 136 (25), 9203−9210. With permission.*

Tao et al. (2014) have prepared PbS QDs-based TiO_2 nanotube arrays (NTAs) through an in situ chemical bath deposition method controlled by low electric field. They could achieve an efficiency of 3.41%. These methods enhance QDs loading on the NTAs with high Voc and fill factor (FF) contributed by shorter electron path, less structural and electronic defects, optimal film thickness ($\sim 4\ \mu m$), and reduced recombination in the ordered TiO_2 NTAs produced by oscillating anodic voltage. Bi et al. (2018) could harvest the short-wave infrared range of the solar spectrum using PbS colloidal quantum dots for solar cells using hybrid inorganic−organic ligand treatment by combining ZnI_2 with 3-mercaptapropionic acid for surface passivation of PbS QDs. The modified PbS solar cell has delivered an efficiency of 7.9% and an additional 3.3% enhancement by placing this cell at the back of the $MAPbI_3$ perovskite film due to enhanced light absorption up to 750 nm. It suggests that the modification of a passivation layer can boost the PCE.

Inorganic nanostructured materials and hybrid carbon materials have attracted a potential interest and open an exciting field in the design and fabrication of efficient catalysts. Guo et al. (2014) have prepared a novel CE consisting of Co_9S_8 nanotube arrays grown on carbon fiber (CF) (Co_9S_8/CF) for fiber-shaped flexible QDSSCs and achieved high PCE of 3.79% as compared to CE and Pt. The redox mediator plays an important role in determining photovoltage and photocurrent in QDSSCs. As per kinetics, reduction of oxidized QDs by the redox mediator should happen faster than the back transfer of electron between TiO_2 and oxidized QDs to sustain the photocurrent. Thermodynamically, the redox mediator should possess effectively

positive reduction potential to provide high photovoltage. Haring et al. (2014) have investigated Mn(II/III) complexes as potential redox mediator for CdS/CdSe/ZnS QDSSCs. Mn poly(pyrazolyl)borates showed high photovoltages ~ 1 V with reduction potential of ~ 0.51 V versus Ag/AgCl. Reduction rates were slower compared to $Co(bpy)_3$, where bpy = 2,2′-bipyridine, which was confirmed by enhanced electron lifetimes up to four orders of magnitude longer as the low solubility prevents the sustaining of high current. The Mn(II/III) complexes redox mediator exhibited higher fill factor (~ 0.6) and photovoltage than $Co(bpy)_3$ and it can be ascribed to more positive reduction potential and reduced recombination.

Interface engineering is an important path to enhance the photovoltaic performance in QDSSCs. Zhang et al. (2019) have studied the interface modification between TiO_2 and QDs using ZnS and ZnSSe semiconductors. Here, the main limitations are the passivation effect and the matching of lattice with TiO_2 and QDs. Though, ZnS has a large energy bandgap due to higher CB edge, its lattice mismatch with TiO_2 and QDs largely leads to the formation of defect states. In contrast, ZnSe alloy exhibited a small lattice mismatch with TiO_2 and QDs with a lower CB edge. They have prepared ZnS_xSe_{1-x} alloy material as a passivation layer on the Zn−Cu−In−Se (ZCISe) QD-sensitized TiO_2 photoanode and reported that alloy material is more constructive for the inhibition of charge recombination between photoanode/electrolyte interfaces, and it also improves extraction of photogenerated electron leading to the photon efficiency improvement from 12.17% to 13.08%.

12.5 Recent developments

Solar cell parameters of some quantum dots-based solar cells are summarized in Table 12.3.

12.6 Conclusion

QDSSCs are a promising alternative for dye-sensitized solar cells due to unique properties of QDs. Numerous factors limit the PCE of QDSSCs, which include narrow absorption of solar spectrum, recombination at interfaces, lower QD deposition on semiconductor film, poor charge carrier transportation, photocorrosion of electrode, and low fill factor, because of the low performance of CE. The research work in QDSSCs has mainly focused on the improvement of PCE in recent years. Among all QDs sensitizers, Cd chalcogenide-based sensitizers, especially CdS and CdSe, are the preferred choice for solar cell devices. The researchers have investigated various modifications to improve the PCE of Cd-based QDSSCs and reported on the cosensitization of CdS/CdSe, introduction of passivation layer (ZnS), annealing temperature, CE modification (Cu_2S, CoS, and composites of Cu_2S/

rGO), polysulfide electrolyte modification and doping of QDs (e.g., Mn), and wide bandgap semiconductor (TiO_2/ZnO). Apart from Cd chalcogenide QDs, other QDs also have promising properties as sensitizers, such as $CuInS_2$, PbS, and Zn-Cu-In-Se. Recently, PQDs and tandem silicon solar cells (PQDs and silicon) have gained significant importance due to the low production cost and high PCE (reported up to 29.5%). To further enhance PCE and to achieve breakthroughs in QDs solar cell device, the focus of investigation should be channeled to research on materials such as doping/composite/different tandem structure of wide bandgap material, QDs, surface treatment of electron transport layer, electrolytes, and CE modification.

13.1 Introduction

Any change in biological or chemical environment is likely to affect the life of human beings, plants, animals, and aquatic plants and organisms. Similarly, humidity and temperature may also affect some physical or chemical phenomena. Therefore sometimes it becomes very much necessary to know the changes in these parameters. The slight variation in chemical environment can affect the health of living beings as some chemicals available in the atmosphere are toxic in nature if present even in very low concentrations. Sometimes, the presence of these chemicals can be fatal also and thus these should be detected in time otherwise any reaction may be totally undesirable. There are some limits on their concentrations, above which these are harmful and they may create disease or harm. Development of any disease or deformation in the body can be detected in advance if a proper sensing system is available. Then, such diseases can be diagnosed in a timely manner and treatment can be started at an early stage. Therefore, such chemical or biological changes should be monitored so as the protect the society from their adverse effects.

The variation of temperature and/or the presence of high humidity also affect some physical or chemical entities adversely, that is, corrosion of metals, stability of hygroscopic compounds, etc., depending on the circumstances. Hence, the correct measurement of humidity and temperature becomes necessary to safeguard certain materials or reactions from high humidity or temperature. Although various sensing systems are commercially available for sensing the presence of some chemical changes such as liquefied petroleum gas, ammonia, alcohol, carbon monoxide, etc., these have some other limits or demerits. Quantum dots (QDs) have some interesting properties like smaller size, large surface area-to-volume ratio, and

Quantum Dots. DOI: https://doi.org/10.1016/B978-0-12-824153-0.00013-6
© 2023 Elsevier Inc. All rights reserved.

fluorescence/photoluminescence, and as a result these QDs can find potential applications in fabricating effective, sensitive, and selective sensors. In this chapter, the development of chemical, biological, temperature, and humidity sensors has been discussed.

13.2 Sensors

QDs can find numerous applications in fabricating sensors such as temperature, humidity, alcohol, hydrogen sulfide, ammonia, carbon dioxide, nitrogen dioxide, pesticides, biosensors, etc.

13.2.1 Chemical sensors

Various chemicals are hazardous in nature and their presence in the atmosphere can affect the lives of human beings, animals, plants, aquatic organisms, etc. They can create a number of dreadful diseases including cancer. Therefore, it is very important to know their presence, even if they are present in very low concentrations. Here, QDs can help us in sensing their presence as their florescence or photoluminescence can be quenched by their presence. Very good and effective sensors are now available involving mainly QDs.

13.2.1.1 Alcohol sensors

A high-performance ethanol sensor based on iron (Fe)-doped titanium dioxide (TiO_2)/molybdenum disulfide (MoS_2) nanocomposite was demonstrated. Wu et al. (2018) synthesized flower-like MoS_2 and Fe-TiO_2 QDs by a facile hydrothermal route. Then they prepared Fe-TiO_2/MoS_2 composite via a layer-by-layer (LbL) self-assembly technique. As-fabricated Fe-TiO_2/MoS_2 film sensor was used to determine different concentrations of ethanol (gas) at room temperature. It was indicated that this sensor has a short response/recovery time, high response, excellent selectivity, stable repeatability, long-term stability, along with detection low limit (ppb level).

Abbasi and Alizadeh (2020) prepared a hybrid of ZnS:Mn^{2+} QDs and soluble N-methylpolypyrrole (NMPPy). It was reported that the determination of methanol can be carried out using as-prepared ZnS:Mn^{2+} QDs/NMPPy hybrid with high selectivity, sensitivity, and a limit of detection of 1 mM in the concentration range of 25−230 mM. As-fabricated hybrid was successfully used to determine the amount of methanol in real samples of alcoholic beverages.

Masemola et al. (2021) synthesized NGQDs via a microwave-assisted hydrothermal method. They used urea and citric acid as nitrogen and carbon sources, respectively. It was reported that uniformly distributed NGQDs (spherical) were obtained in 4 min. Then these dots were further loaded onto PANI/PAN to fabricate NGQDs/PANI/PAN composite. It was observed that

optimized electrospun composite fibers can be used for sensing of alcohol vapors.

13.2.1.2 Liquid petroleum gas sensor

Liquid petroleum gas-sensing behavior of graphene/SrO QDs composites was also investigated by Nemade and Waghuley (2013a). They evaluated gas-sensing properties of composites by the change in resistance as a function of gas concentration of LPG.

They also synthesized graphene/Bi_2O_3 QDs composites (Nemade and Waghuley 2013b). It was reported that as-prepared composites exhibited better performance toward the sensing of LPG. The graphene/CeO_2 QDs composite was synthesized by Nemade and Waghuley (2013c). They used this composite for sensing of liquid petroleum gas at room temperature. This composite of graphene/CeO_2 QDs was prepared on mixing 20 wt.% of graphene in CeO_2 (1 g). This composite shows excellent stability and sensing response.

Mishra et al. (2015) synthesized rGO/SnO_2 QDs and investigated its LPG gas sensing behavior. It was reported that this sensor exhibited a high response of ~92.4% to LPG (500 ppm) at 250°C. As-fabricated rGO/SnO_2 QDs-based sensor also has a good selectivity for LPG even in the presence of other chemicals such as chloroform, ammonia, benzene, toluene, acetone, formic acid, acetic acid, and *n*-butylacetate. It was observed that the gas response to LPG was about 17.8 times higher compared to formic acid. An excellent reproducibility was also observed in this sensor. Zhang et al. (2018b) prepared zinc oxide/polypyrrole/lead sulfide QDs (ZnO/PPy/PbS QDs) nanocomposite film and used it as a liquefied petroleum gas sensor. It was reported that it can detect LPG and the response at 1000 ppm LPG could reach 45.47%. It was also revealed that it showed excellent repeatability and good selectivity.

13.2.1.3 Ammonia (NH_3) sensors

Liu et al. (2016) prepared PbS QDs/TiO_2 nanotubes arrays (PbS QDs/TiO_2 NTARs) via ionic-layer adsorption. Then they fabricated a gas sensor for ammonia based on these. It was observed that PbS QDs/TiO_2 NTARs had a good response toward ammonia gas and could detect 17.49−100 ppm ammonia with a limit of detection of 2 ppm. It was also revealed that as-fabricated PbS QDs/TiO_2 NTARs show good selectivity toward ammonia as compared with methanol, ethanol, acetone, and toluene.

Hollow indium trioxide nanofibers were fabricated by Hong et al. (2021) via a combination of electrospinning and high-temperature calcinations. Then these were coated with nitrogen-doped graphene QDs (N-GQDs). As-prepared N-GQD-coated hollow In_2O_3 nanofibers served as a core for synthesizing polyaniline (PANI)/N-GQD/hollow In_2O_3 nanofiber ternary

composites using in situ chemical oxidative polymerization. It was observed that the response value of the PANI/20%N-GQD/hollow In_2O_3 nanofiber sensor was 15.2 on exposure to 1 ppm ammonia. This was almost 4.4 times more than the PANI sensor. It was revealed that this composite sensor proved to be very sensitive in the detection of NH_3 in the concentration range of 0.6−2.0 ppm at room temperature. This sensor also exhibited higher selectivity and repeatability in the range of 1.0−2.0 ppm NH_3. Hence, it was suggested that it will prove to be a good gas-sensing material in the case of human breath for detecting hepatic or kidney disease.

Kumar et al. (2018) fabricated poly(3, 3-dialkylquaterthiophene) (PQT-12) and CdSe QDs composite. It was based on back-gated organic thin-film transistors (OTFTs) SiO_2-coated heavily doped p-Si substrates. It was reported that an estimated gas response of ∼51% was obtained for sensing ammonia gas using a PQT-12/CdSe QDs composite, which was higher than an OTFT pristine PQT-12 OTFT-based sensor (41%). Liu et al. (2018) self-assembled 3-D cocoon-like architectures of PbS QDs−reduced graphene oxide composites. It was observed that 3-D PbS QDs/rGO nanococoons exhibited a good detection limit of 750 ppb toward sensing ammonia gas at room temperature, which was higher than rGO and pure PbS QDs. It was also revealed that these 3-D PbS QDs/rGO nanococoons show a good selectivity toward ammonia gas compared to ethanol, acetone, etc. with excellent sensing stability in the long term.

Ouyang et al. (2018) prepared monolayer WS_2 NSs modified with Pt QDs. It was reported that the response of nanocomposite to NH_3 (250 ppm) was almost ten times that of WS_2 NSs. Liu et al. (2019) self-assembled $CuSbS_2$ QDs/reduced graphene oxide composites via a hot-injection method. It was reported that a gas sensor based on $CuSbS_2$ QDs/rGO composites exhibited a good response toward ammonia with a limit of detection of 500 ppb with an average response time of 50 s at room temperature. It was revealed that the sensing performance of the composites was improved in the presence of visible light.

Wongrat et al. (2021) prepared ZnO nanostructures combined with GQDs. It was reported that GQDs have an average size distribution of 2.6 nm. It was revealed that as-prepared ZnO:GQD heterojunctions exhibited a selective response (high) to the vapor of ammonia. As-fabricated ZnO: GQDs sensors have the optimum sensor response at an ammonia concentration of 1000 ppm. This sensor was found to be highly responsive and gave a selective performance for sensing ammonia at room temperature. Bai et al. (2022) prepared flower-like MoS_2 decorated with SnO_2 QDs via a solvothermal method. It was reported that SnO_2 QDs have a uniform particle size of 2−4 nm and these were uniformly distributed on the ultrathin nanosheets of MoS_2 hierarchical architectures. It was found that as-prepared SnO_2 QDs@MoS_2 composites-based gas sensor exhibited a good response of 8.6 with short response and recovery times of 6 s/121 s, respectively to 100 ppm

ammonia with good selectivity, excellent repeatability, and outstanding long-term stability.

13.2.1.4 Hydrogen sulfide (H_2S) sensors

Keshtkar et al. (2018) synthesized SnO_2 QDs−fullerene (SnO_2 QDs-C_{60}) nanohybrid via a hydrothermal method. It was observed that the as-prepared hybrid could detect H_2S (70 ppm). This sensor exhibited a good selectivity toward H_2S gas in the range 5.4−70 ppm. Dun et al. (2019) prepared CdS QDs supported by ultrathin porous nanosheets and further assembled into hollowed-out Co_3O_4 microspheres (CdS QD/Co_3O_4 HMSs). It was observed that CdS QDs of ∼4.5 nm size were well dispersed on Co_3O_4 HMSs (ultrathin porous nanosheet). It was reported that this sensor exhibited a high response (12.7) for 100 ppm H_2S as well as fast response and recovery rates of 0.6−1.0 s, respectively.

Yang et al. (2019) prepared In_2O_3 colloidal QDs and then they deposited In_2O_3 QDs followed by surface ligand exchange treatment via Cu inorganic salts to fabricate H_2S sensor devices. It was reported that the as-prepared sensor exhibited a high response up to 90 for H_2S (5 ppm) with response and recovery time of 72 and 200 s, respectively. Xu et al. (2021) prepared carbon dots passivated with polyethylene glycol. These were then used for detection of H_2S. This proposed sensor can detect Na_2S with a concentration limit of detection approximately 7.0 nM. It was proposed that this probe can also be used successfully for the detection of H_2S in live cells.

13.2.1.5 Carbon dioxide (CO_2) sensors

Chu and Hsieh (2019) designed an optical fiber carbon dioxide sensor, which was based on the emission wavelength shift of $CuInS_2$/ZnS QDs. It was all due to changes in the absorption of α-naphtholphthalein (a pH indicator). With a change in concentration of CO_2. It allowed the detection of CO_2 concentration over the range of 0%−100%. Bhakat et al. (2021) assembled ZnO QDs. It was reported that as-prepared ZnO QD−phosphate was successfully used for designing a gas sensor that showed great sensitivity and selectivity toward CO_2 gas at room temperature. Hajikhanloo et al. (2021) created a valley in the core of the ring and then PbSe QDs were deposited in this valley. This sensor was used to detect CO_2 gas. It was reported that the refractive index of PbSe QDs was found to increase with the increase in the concentration of gas flow. It was revealed that the as-prepared sensor operated in a wide range of concentrations for CO_2 gas with a detection limit of 0.001%.

13.2.1.6 Nitrogen dioxide (NO_2) sensors

Wang et al. (2013) functionalized silica aerogels branched polyethyleniminecapped QDs. The fluorescence quantum yield of CQD-aerogel hybrid material yield was more than 40%. Its fluorescence was sensitively and

selectively quenched by NO_2 gas. Dong et al. (2018) synthesized germanium QDs (GeQDs)/graphene hybrids. They fabricated a NO_2 gas sensor by introducing GeQDs on graphene and the gas sensor sensitivity to NO_2 was improved substantially. With the optimization of the growth time of GeQDs (600 s), the response sensitivity to 10 ppm NO_2 can be as high as 3.88, which is 20 times higher than that of the graphene sensor without GeQDs decoration. The 600 s GeQDs/graphene hybrid sensor exhibited fast response and recovery rates as well as excellent stability.

Lv et al. (2021) prepared SnO_2 hierarchical hollow cubes (ultrathin mesoporous nanosheets) and then N-GQDs were decorated on the surface of SnO_2. It was reported that as-prepared N-GQDs modified SnO_2 (NG/Sn_x) exhibited an improved response toward 1 ppm NO_2, which was almost 2.2 times that of pure SnO_2. Thus sensing material exhibited long-term stability, fast response, recovery repeatability, and good selectivity. This NG/$Sn_{1.5}$ sensor can even detect lower concentrations of NO_2 at the level of 100 ppb.

Zhang et al. (2021) modified ZnO composite with N-GQDs. The sample G-Z-2 (N-GQD_S doping amount of 2 mL) exhibited excellent sensing performance for NO_2 compared with pure ZnO. It was found to be sensitive to 5 ppm NO_2, which was 11.6 times more than others. The detection limit of NO_2 was found to be 0.1 ppm. It was also revealed that there is selectivity, excellent reproducibility, and stability in this sensor for the detection of NO_2. Luo et al. (2022) modified MoS_2 with SnO_2. The MoS_2 nanoflowers were prepared via a hydrothermal method with a high surface/volume ratio and SnO_2 was fabricated using a solvothermal method. It was revealed that its response was increased by 1.5 times on modification, supported by fast response and recovery time for sensing of NO_2 gas.

13.2.1.7 Pesticide sensors

Liang et al. (2021) developed a fluorescence/colorimetric sensor, which was based on a nanocomposite of carbon QDs and gold nanoparticles (CQDs-GNPs). It was observed that fluorescence intensity increased, but absorption decreased with the addition of malathion, a pesticide. Finally, the approximate concentrations of malathion in cabbage samples were estimated by the standard arrays and the naked eye. It was revealed that malathion can be accurately detected in cabbage samples with two methods with recoveries of 89.9%−103.4% (fluorescence) and 88.7%−107.6% (colorimetric).

Nair et al. (2020) prepared a fluorescent sulfur-doped GQDs (S-GQDs)-based sensor. It was reported that the particle size distribution was uniform in the order of $\sim$5 nm with high crystallinity. It was revealed that green fluorescent S-GQDs exhibited a detection limit of 0.45 and 1.6 ppb for carbofuran and thiram, respectively. A sensor was developed by Liang et al. (2021) that was based on CQDs-GNPs. It was observed that fluorescence intensity was increased on the addition of malathion in the range of 1×10^{-9}

to 1×10^{-2} M. It was reported that concentrations of malathion in cabbage samples can also be determined. Alvandi et al. (2021) prepared multicolor fluorescent carbon dots via a hydrothermal method using greengage plums. These carbon dots were used to detect pesticides (duplosan, confidor, and dialen super). It was also revealed that the as-prepared nanosensor did not detect other pesticides such as diazinon, bromoxynil, malathion, glyphosate, and deltamethrin, confirming that it is sensitive and specific toward the three intended pesticides.

Ghiasi et al. (2021) fabricated a selective and sensitive electrochemical sensor based on the modification of activated glassy carbon electrode with nickel molybdate GQDs, and chitosan nanocomposites. It was reported that the as-fabricated sensor can be used in a concentration range between 0.1 and 330 μM with a limit of detection of 30 nM. The function of the sensor was also evaluated for the recovery analysis of diazinon in real samples of tomato and cucumber.

Yellowish-green emitting CQDs were prepared by Huo et al. (2021) via hydrothermal treatment. They used p-phenylenediamine and citric acid as precursors. It was observed that phoxim can quench the fluorescence emission of CQDs by an inner filter effect. As-prepared CQDs showed a good selectivity and sensitivity for detection of phoxim in the concentration ranges of 1−10 and 10−98 μM with a detection limit of 0.09 μM. It was revealed that phoxim can also be detected in real samples with satisfactory recoveries ranging between 93% and 105.9%. The low cytotoxicity and excellent biocompatibility of these CQDs was suitable for cell imaging also.

Yang et al. (2021b) synthesized cadmium telluride QDs. As-prepared CdTeQDs exhibited good water dispersion bright emission, and long emission wavelength as well as a unique response inhibition of organophosphorus pesticides (OPs) on acetylcholinesterase (AChE) activity. It was reported that the detection of OPs can be done with sensitivity, with the limit of detection of 0.027 ng mL^{-1}. It was observed that a CdTe-QD-based sensor can monitor methidathion in cultivated soil as well as Chinese cabbage.

Yi et al. (2021) first modified molybdenum disulfide QDs (MoS_2 QDs) with 3-aminophenyl boronic acid, and then it was functionalized with hydropropyl-β-cyclodextrin (β-CD), (β-CD functionalized MoS_2 QDs β-CD-MoS_2 QDs). It was used for fluorescent detection of parathion-methyl (MP), hydrolyzed to p-nitrophenol which can enter into the β-CD cavity; thus resulting in fluorescence quenching. It was reported that as-prepared β-CD-MoS_2 QDs nanoprobe exhibited a wide detection range of 0.01−18.0 ppm and a low detection limit of 3.3 ppb for the detection of parathion-methyl. An excellent selectivity was also reported for detection of MP, and it can be applied in real samples. Fluorescent CQDs (J-CQDs) were prepared by Chandra et al. (2022) using jatropha fruit via a hydrothermal route. The catalytic activity of AChE was inhibited in the presence of OPs, and a fluorescence signal was recovered. A sensitive and selective nanoprobe was designed as a sensor,

which can detect chlorpyrifos with a limit of detection (2.7 ng mL^{-1}). It was also revealed that this can be applied for pesticide detection in environmental and agricultural samples successfully with acceptable recovery.

13.2.1.8 Others

Lu et al. (2019) prepared a carbon dot-decorated hybrid nanocomposite (CD@RCC3) (chiral porous organic cage) and used it to fabricate a fluorescent sensor. It was reported that the as-fabricated sensor was used for the determination of isomers of nitrophenol. It could also differentiate phenylethanol and phenylalaninol enantiomers.

Yang et al. (2021c) prepared CdTeS QDs-coated silica shell (CdTeS QDs@SiO_2). Then ZnCdS QDs were encapsulated in a 3D network imprinted polymer (ZnCdS QDs@MIP) to give a response signal. It was observed that the fluorescence emission of ZnCdS QDs@MIP was quenched in the presence of ascorbic acid (1−500 μM) with a detection limit of 0.78 μM. It was reported that satisfactory results were obtained in the detection of ascorbic acid in vitamin C tablets.

Liu et al. (2021) designed an ECL sensor based on a dual-emission luminophore (NSGQDs-PEI-luminol-Pt). It was composed of nitrogen and sulfur codoped GQDs (NSGQDs) (main luminophore), luminol (auxiliary luminophore), platinum nanoparticles (coreaction accelerator), and polyetherimide linker of NSGQDs and luminal, respectively. This ECL senor can detect ascorbic acid in the concentration range of 10−360 nM with a limit of detection of 3.3 nM. It was also used for monitoring ascorbic acid in human serum.

Yanyan et al. (2021) fabricated a sensor based on N-GQDs. This sensor was used for the detection of H_2O_2 and glucose in the concentration range of 0.3−100.0 and 0.7−90.0 μM with a limit of detection of 63 nM. The sensitive detection of glucose is also realized in the concentration range (0.7−90.0 μM) with LOD of 96 nM, because the oxidation of glucose by glucose oxidase (GOx) produces H_2O_2.

A fluorescence sensor with dual-emission was developed by Gan et al. (2021) based on CQDs and Eu^{3+} complexes. It was observed that dual-emission fluorescence intensity was increased in the presence of Hg^{2+} ions. It was reported that the as-developed sensor exhibited an excellent sensitivity and selectivity in the concentration range of 1−20 nM with a detection limit of 0.2 nM. It was revealed that this sensor gave satisfactory recovery from 97.6% to 105.4% for the detection of Hg^{2+} ions in drinking water and milk samples.

A single-step synthesis of positively charged Pd NPs and green synthesis of GQDs from graphite was reported by Ahmed et al. (2021). An aptamer-induced fluorescence fluctuation of GQDs and palladium nanoparticles for the detection of tetracycline has been observed with a limit of detection of

45 ng mL^{-1}. CQDs were synthesized via a facile one-step hydrothermal treatment of purslane leaves by Amer et al. (2021). It was reported that a CQDs-based sensor could detect formaldehyde. It was revealed that the as-fabricated sensor exhibited a good reversibility and reproducibility.

Carneiro et al. (2021) synthesized CQDs via a hydrothermal route using the seed of *Caelsalpinia pulcherrima*. They could detect five food additives—lactic acid, citric acid, ascorbic acid, potassium sorbate, and sodium benzoate—with a detection limit of 252 ng mL^{-1}. They also successfully identified all these additives in a sample of a pickled olives with 100% of the combinations correctly identified.

Huangfu and Feng (2021) synthesized $CsPbBr_3$ QDs and used them to sense various solvents with different polarities. A good linear relationships was found between the fluorescence intensity of $CsPbBr_3$ QDs and the volume of different polar solvents, ethanol, methanol, and acetone. It is all due to the fast change of polarity, which makes perovskite QDs useful as polarity sensors. They used as-fabricated $CsPbBr_3$ QDs for total polar materials detection in edible oils. The quenching effect of fluorescence intensity was observed for soybean oil, olive oil, and sunflower oil, in the range of 17%−31.5%, 25%−31.5%, and 21.5%−33%, respectively.

Khose et al. (2021) synthesized novel red-fluorescent GQDs (G-GQD) using therapeutic guava (*Psidium guajava*) leaf. It was reported that the emission property of as-fabricated G-GQD can be used as a fluorescence turn-off probe for the determination of Hg^{2+} ions with a detection limit of 82 μM. It was also reported that other ions such as Co^{2+}, Cu^{2+}, Al^{3+}, and Fe^{2+}, are also known fluorescence quenchers, but they did not show any interference with the selectivity of Hg^{2+} ions. The G-GQD can be used as a sensor for Hg^{2+} ions even in polluted water sources.

Kongsanan et al. (2021) synthesized GQDs by pyrolyzing solid citric acid. The as-prepared sample can be used for the simultaneous detection of ferricyanide $[Fe(CN)_6]^{3-}$ and cyanide (CN^-) in wastewater samples (Fig. 13.1). It was reported that the fluorescence intensity of GQDs decorated with Hg^{2+} could be turned on in the presence of CN^- and back to turn-off mode by $[Fe(CN)_6]^{3-}$. These can be detected simultaneously in the range of 5.0−15.0 and 10.0−50.0 μM, with detection limits of 3.10 and 9.48 μM for CN^- ion and $[Fe(CN)_6]^{3-}$, respectively. This sensor was successfully used for CN^- and $[Fe(CN)_6]^{3-}$ detection (simultaneous and selective) in wastewater samples of municipal water reservoirs.

Lu et al. (2021) fabricated functionalized carbon nitride QDs (CNQDs) using a microwave-assisted solvothermal method. It was reported that these CNQDs were monodispersed with a narrow size distribution of particles with an average size of 3.5 nm. They exhibited excellent sensitivity and selectivity of fluorescence quenching for 2,4,6-trinitrophenol (TNP) in the range of 0.1−15 μM with a limit of detection of 87 nM. They also obtained satisfactory results with this probe for detecting TNP in spiked water samples.

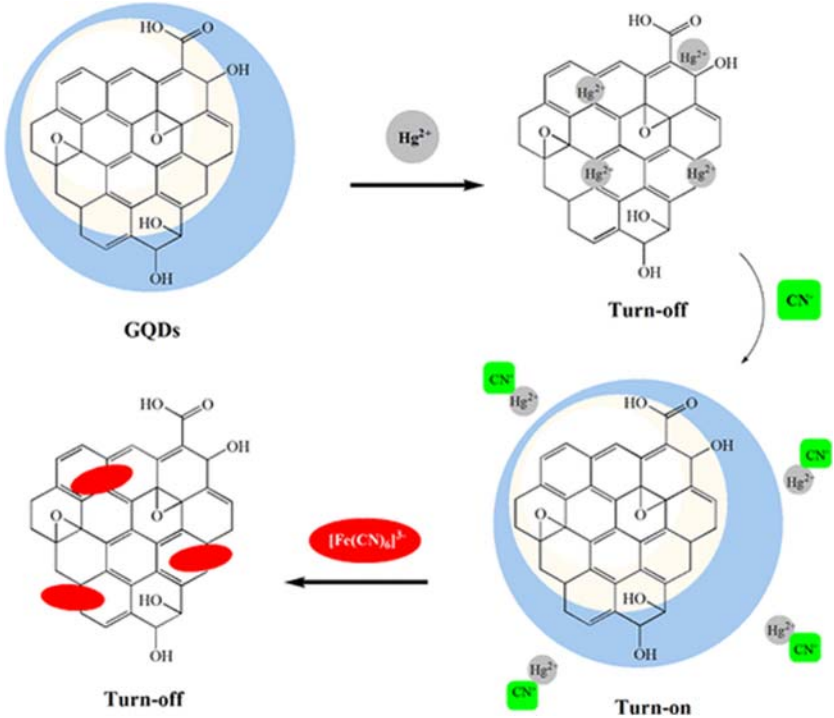

FIGURE 13.1 Use of GQDs for detection of ferricyanide and cyanide ions. *Adapted from Kongsanan, N., Pimsin, N., Keawprom, C., Sricharoen, P., Areerob, Y., Nuengmatcha, P., et al., 2021. A fluorescence switching sensor for sensitive and selective detections of cyanide and ferricyanide using mercuric cation-graphene quantum dots. ACS Omega 6(22), 14379–14393, with permission.*

Mehata and Biswas (2021) prepared GQDs–silver nanoparticles (GQDs@AgNPs) hybrid structure using GOD as a reducing and stabilizing agent. As-prepared composite exhibited strong surface plasmon resonance along with the absorption of GQDs. It was also reported in the sensing of hydrogen peroxide in an aqueous medium and therefore as-prepared GQDs@AgNPs nanohybrids can be used as a sensing probe.

The mannitol capped boron-doped CQDs (B-CQDs) were synthesized by Ali et al. (2021) and used for detection of sparfloxacin and orbifloxacin. As-prepared samples exhibited an increase of fluorescence intensity in the range of 1.5×10^{-9}–1.3×10^{-7} and 1.2×10^{-9}–1.1×10^{-7} M with limits of detection of 5.0×10^{-10} and 4.0×10^{-10} M for sparfloxacin and orbifloxacin, respectively. This probe gave satisfactory results determination for these antibiotics in milk and natural water samples. Zhang and Fan (2021) synthesized cerium–nitrogen codoped CQDs (Ce–N–CDs) via a hydrothermal method. They used cerium nitrate with citric acid, and ethylenediamine.

It was observed that as-prepared Ce−N−CDs exhibited excellent detection selectivity for tetracyclines (TCs). It was reported that this probe detected doxycycline (DC) in a concentration range of 0.4−35 μM with a limit of detection of 0.25 μM. This method was also used successfully for the determination of DC and total TCs in pork and milk. It was revealed that as-prepared Ce−N−CDs had low cytotoxicity and did not affect cell viability. It was proposed that as-prepared Ce−N−CDs can be used in cell imaging.

A dual-signal fluorescent sensor was developed for the detection of tetracycline in milk with excellent reproducibility and stability. Molybdenum disulfide QDs (blue fluorescence) and cadmium telluride QDs with yellow fluorescence were synthesized by (Liang et al., 2022). They prepared MoS_2/CdTe-based sensor with two fluorescence emission peaks at 433 and 573 nm. It was observed that the fluorescence of MoS_2/CdTe was quenched by photoinduced electron transfer. As-prepared CdTe QDs composite can be used for the determination of tetracyline in the concentration range of 0.1−1 μM. This sensor was also applied for the detection of tetracyline in milk samples with recovery of 95.53%−104.22%.

Şen et al. (2022) synthesized fluorescent polyethylenimine capped CQDs (PEI-C-dots) via microwave irradiation. They used polyethylenimine and citric acid as precursors for this purpose. It was observed that fluorescence quantum yield of as-synthesized PEI-C-dots was found to be 54% and the detection limit for 2,4,6-trinitrotoluene was 93 $\mu g\ L^{-1}$. It was interesting to note that that neither the HMX or RDX explosives interfered with this determination. Xu et al. (2022) prepared molecularly imprinted polymers based on Si QDs (Si QDs@SiO_2 @MIPs) via a sol−gel method. It was observed that as-prepared Si QDs@SiO_2 @MIPs exhibited a strong fluorescent emission at 447 nm, which was quenched in the presence of catechol. This sensor can be used to determine concentrations of catechol in the range of 0.018−100 μM with a limit of detection of 0.018 μM. This method was also applied by detecting catechol in real river water samples with satisfactory results.

Afshary et al. (2022) fabricated an electrochemiluminescence sensor based on nitrogen-doped CQDs (N-CQDs). It was reported that the as-prepared N-CQD-based sensor can be used for the determination of ceftazidime in the concentration range of 1×10^{-7} to 5×10^{-4} mol L^{-1} with a limit of detection of 2.3×10^{-8} mol L^{-1}. It was suggested that this ECL sensor is also applicable for the analysis of ceftazidime in some real samples (milk powder, bovine milk, and human serum).

Jiang et al. (2022) decorated 0D/2D heterostructure of ZnO QDs on nitrogen-doped Ti_3C_2 MXene (ZnO/N-Ti_3C_2). The size of ZnO QDs was found to be in the range of 2−5 nm. It was reported that the as-prepared sensor could be used for selective and sensitive detection of chloramphenicol in the concentration range of linear range (0.1−100 ng mL^{-1}) with a detection limit of 0.019 ng mL^{-1}. Praoboon et al. (2022) developed an

electrochemiluminescence sensor using tris(2,2′-bipyridyl)ruthenium(II) complex coupled with water-soluble thioglycolic acid-capped CdSe QDs. It was revealed that the trimethylamine can be determined using this sensor in the concentration range of 1×10^{-12} to 1×10^{-7} M with a limit of detection of 2.09×10^{-13} M. A rapid estimation of concentration of trimethylamine can be done in fish tissue using the as-prepared sensor.

13.2.2 Biosensors

Any disease has its origin in changes in biological environment and organs of the body, and therefore detecting such changes at an early stage can safeguard our health because one can plan the treatment of any disease in a timely manner. It is possible to sense these changes with the help of QDs, which are very sensitive to any variation in the biological environment.

Hwang et al. (2021) reported the synthesis of reduced graphene oxide QDs (rGOQDs) in perfluorotributylamine solution. It was observed that the as-prepared sample exhibited good photostability without any loss in intensity even after a month and it can be used for an optical device (Fig. 13.2). It was revealed that PL spectra from the rGOQDs-solution changed color from blue to green when mixed with GOx for glucose concentration of 0−2 mM. Thus rGOQDs can be used as colorimetric biosensors with the help of smartphone.

Mostafa et al. (2021) synthesized highly photoluminescent $Mn^{2+}{}_xZn_{2-x}S$ ($0 \leq x \leq 0.1$)-doped QDs. These QDs were capped with 3-mercaptopropionic acid. It was reported that ZnS and $Mn^{2+}{}_{0.04}Zn_{1.96}S$ QDs were of average particle size 13 and 16 nm, respectively. As-prepared Mn-doped ZnS QDs were used as an optical sensor for determination of bovine serum albumin with limit of detection of 1.56×10^{-7} M.

Pothipor et al. (2021) constructed an electrochemical biosensor based on gold nanoparticles/GQDs/graphene oxide (AuNPs/GQDs/GO) modified three-screen-printed carbon electrode to detect miRNA-21, miRNA-155, and

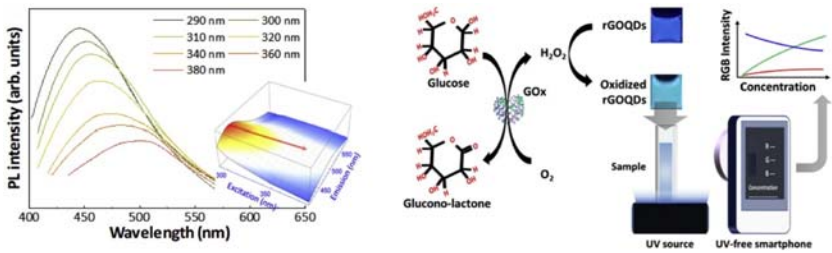

FIGURE 13.2 Use of reduced graphene oxide quantum dots in detection of glucose. *Adapted from Hwang, J., Le, A.D.D., Trinh, C.T., Le, Q.T., Lee, K.G., Kim, J., 2021. Green synthesis of reduced-graphene oxide quantum dots and application for colorimetric biosensor. Sens. Actuators A: Phys. 318. https://doi.org/10.1016/j.sna.2020.112495, with permission.*

miRNA-210 biomarkers. They used different redox species (polydopamine, anthraquinone, and methylene blue) as redox indicators for anchoring to capture miRNA probes, which are hybridized with the miRNA-21, miRNA-155, and miRNA-210. It was reported that the as-developed AuNPs/GQDs/GO-based biosensor exhibited an excellent performance for miRNA sensing simultaneously, in a wide concentration range (0.001−1000 pM) with a lower detection limit of 0.04, 0.33, and 0.28 fM for the detection of miRNA-21, miRNA-155, and miRNA-210, respectively. It was revealed that this method can be used with selectivity for the detection of miRNAs in human serum samples and such a multiplex label-free miRNA biosensor has a great potential for the diagnosis of breast cancer.

Van Tam et al. (2021) synthesized aniline functionalized GQDs (a-GQDs) via microwave-assisted pyrolysis of fructose. Then these GQDs were modulated with phenylboric acid (PBA). It was reported that the as-prepared fluorescent sensor using a-GQDs/PBA exhibited high selectivity and sensitivity toward glucose. Furthermore, a-GQD/PBA system exhibited excellent biocompatibility and can be satisfactorily applied to detect glucose in HeLa cells with a limit of detection of 2.1 μM. A highly compatible graphene nanofilm decorated with Prussian blue (PB) (electroactive) and photoelectric responsive QDs was prepared by Ma et al. (2022). An impressive biosensing performance could be obtained by as-prepared enzyme-modified PB-rGO-QDs film, which exhibited high sensitivity for H_2O_2. It was reported that wearable devices of PB-rGO-QDs films on textile showed flexible bending lifetime over several thousands of cycles, with photoelectronic properties and as a stable sensor.

A sensitive photoelectrochemical biosensor was fabricated by Tu et al. (2022) with ZnSe QDs (QDs)/Au nanoparticles. It was reported that ZnSe QDs were enhanced in the presence of light irradiation as a result of surface plasmon resonance of AuNPs. The photocurrent intensity of AuNPs/ZnSe QDs was also increased by six times that of ZnSe QDs only. This biosensor was able to detect target DNA in the range from 1 fM to 10 nM with a very low limit of detection of 0.33 fM. Acrylamide (AM) is a potential carcinogen produced during food thermal processing. Wei et al. (2021) developed a simple fluorescent biosensor that was based on single-stranded DNA (ssDNA). CQDs and ssDNA were preferentially bound to AM by hydrogen bonding. It was observed that the degree of reduction of fluorescence was smaller compared to in the absence of AM. This sensor could detect AM in the concentration range of 5×10^{-3} to 1×10^{-7} M with a detection limit of 2.41×10^{-8} M.

Deng et al. (2022) fabricated CQD functionalized solution-gated graphene transistors and used them for highly sensitive label-free detection of DNA. These CQDs were immobilized on the surface of the gate electrode using mercaptoacetic acid using its thiol group. The ssDNA probe can hybridize with the ssDNA target and form double-stranded DNA. It was

revealed that the detection limit was as low as 1 aM. The proposed sensor exhibited a good linear range (1 aM to 0.1 nM). It was interesting to note that it can effectively distinguish one-base mismatched target DNA and response time was only 326 s for 1 aM target DNA molecules. Mao et al. (2022) coated colloidal gold nanoparticles with polydopamines (PDA) to obtain Au@PDA nanoparticles. It was reported that Au@PDA nanoparticles mediated ZnCdSe/ZnS QDs fluorescence quenching and recovery, and it could assist in the detection, resulting in a reverse fluorescence enhancement detection format of carbendazim (CBD). It was observed that the sensitivity of lateral flow immunoassay (LFIA) of the fluorescence was 32 times higher compared to the colorimetry mode. A negligible cross reactivity was there for the determination of thiabendazole, benomyl, thiophanate-methyl, and thiophanate-ethyl on using LFIA. They could achieve satisfactory results in testing spiked strawberry and cucumber samples, which indicated that the as-prepared probe Au@PDAs-QDs-LFIA was more reliable.

The 3-mercaptopropionic acid capped CdSe QDs graphene nanocomposite (rGO-CdSe QDs/ITO) was fabricated by Khandelwal et al. (2022) and used as an electrochemical biosensor for the detection of low-density lipoprotein (LDL). It was reported that as-prepared immunoelectrodes could detect LDL in a wide concentration range ($2-125\ \text{mg dL}^{-1}$). Zhu et al. (2022) prepared CdTe QDs (CA-CdTe QDs) (cysteamine stabilized) and gold nanoparticles (sodium citrate stabilized). These CA-CdTe and Au NPs were self-assembled to from large clusters. The fluorescence of CA-CdTe was quenched as a result of fluorescence resonance energy transfer (FRET). It was reported that positive glutathione (GSH) could assemble with negative Au NPs through electrostatic interaction at pH 5.5 and it could destroy the FRET system of CA-CdTe and Au NPs. The recovered fluorescence efficiency of CA-CdTe shows a linear relationship with GSH concentrations in the range of 6.7 nM to 0.40 μM, with a limit of detection of 3.3 nM. It was revealed that this sensing system can be applied in the detection of GSH in real human blood plasma samples with good recovery (99.5%−102.3%).

13.2.3 Humidity sensors

Humidity of an area is a necessary parameter for knowing the moisture content, which can sometime adversely affect some materials. Therefore it is important to know about humidity. Various sensors are available for determining humidity in a particular area, but QDs can measure humidity more selectively as these are very sensitive toward any change in humidity.

Chaloeipote et al. (2021) synthesized GQDs and silver nanoparticles via a hydrothermal method and a green reducing agent route, respectively. They confirmed the successful formation of a core/shell-like AgNPs/GQDs structure. It was reported that a ratio of 1:1 of GQDs/AgNPs in nanocomposite exhibited the best humidity response of about 98.14%. Chaudhary et al. (2021)

synthesized CQDs of two types: (1) C-1 and (2) C-2, depending on carbonization temperatures. It was revealed that average particle size was 5.5 and 2 nm for samples C-1 and C-2, respectively. It was reported that C-2 gave an enhanced sensing performance with an average sensitivity of 254.861 pF/%RH with a fast response and recovery times of 7.3 and 4.7 s, respectively. Holemadlu et al. (2022) synthesized GQDs via carbonization of citric acid monohydrate. This process is low cost and has scalability. They fabricated a humidity sensor using GQD solution as the sensing material, which showed a rapid and high sensitivity to changes in humidity.

13.2.4 Temperature sensors

Temperature variation is a quite common feature but it is likely to affect some chemical and biochemical reactions, and therefore the correct measurement of temperature becomes necessary. Although various techniques are available for temperature measurement, QDs are very sensitive to such temperature changes and these are used in different devices for determining temperature at a particular site.

Zhang et al. (2018a) prepared lead sulfide QDs decorated zinc oxide nanorods. Then PbS QDs/ZnO film was fabricated by tuning deposition of PbS QDs on ZnO nanorods via a successive ionic-layer adsorption and reaction (SILAR) method. The sensor based on PbS QDs/ZnO nanorods can be used for sensing of room temperature.

Glass stabilized Mn-doped $CsPb(Cl/Br)_3$ QDs have been synthesized by Zhuang et al. (2019). They used a glass composition design and in situ glass crystallization for this purpose. It was reported that Mn-doped $CsPb(Cl/Br)_3$ QDs exhibited superior thermal stability and water resistance (about 100%). It is interesting to know that complete luminescence could be retained even after immersing this composite in water for a month or so. It was revealed that rapid thermal quenching for exciton recombination relative to Mn^{2+} d−d transition at lower temperatures (cryogenic) may provide it a promising position as a ratiometric temperature sensing medium.

Li et al. (2020) developed an optical thermometer with high sensitivity by using exciton recombination of $CsPbBr_3$ QDs for detecting a signal for temperature. It was reported that the fluorescence intensity ratio of exciton recombination and Eu^{3+} emission in nanocomposite exhibited a good temperature sensing property in as-prepared temperature ranging between 93K and 383K. It was observed that maximum absolute and relative temperature sensitivity could reach 0.0224% and $2.25\%K^{-1}$, respectively. It provides an effective pathway for developing a noncontact optical thermometric materials.

A simple one-pot strategy was reported by Lei et al. (2021) for preparing polyvinyl alcohol (PVA)-capped SQDs. They used low cost sulfur and PVA as a ligand. It was observed that as-prepared SQDs had sizes in the range of

1.5−5 nm. They also exhibited good water dispersibility and stability, good optical stability, bright fluorescence, and low cytotoxicity. As-prepared SQDs show selective and sensitive fluorescence quenching behavior toward Fe^{3+} ions with a detection limit of 9.2×10^{-9} M. SQDs also show temperature-dependent fluorescence. It was revealed that SQDs can be used for monitoring Fe^{3+} ions and also as a nanothermometer for temperature in the interior of cells.

Han et al. (2021) fabricated a highly sensitive ratiometric thermal sensor. This sensor was based on colloidal C-dots as these C-dots exhibited a temperature-dependent photoluminescence response. It was reported that C-dots@OH exhibited an absolute thermal sensitivity of $-0.082\ ^{\circ}C^{-1}$, which makes it a very promising candidate for high-sensitivity, and a self-calibrated nanoscale thermometer. These as-prepared C-dots@OH were used to monitor the intracellular temperature in the range of 32°C−42°C, with a clear trend for temperature variation in a single cell. It was reported that as-prepared thermal sensors can find potential application in nanoelectronic and optoelectronic devices.

Lee et al. (2021) developed nanothermometers based on luminescence of GQDs to probe temperature-sensitive processes at the nanoscale,. These QDs were synthesized via top-down (RGQDs) or bottom-up (N-GQDs) approaches using reduced graphene oxide and glucosamine as precursors, respectively. The average particle size of QDs was found to be 3−6 nm. It was reported that both GQDs exhibited temperature-sensitive fluorescence, which was photostable. A linear as well as reversible fluorescence quenching was observed up to 19.3% for the visible and near-infrared GQD emission in the temperature range 25°C−49°C. It was revealed that these GQD nanothermometers can give more than 40% quenching response in the range of 25°C−45°C, when internalized into the cytoplasm of HeLa cells. It was suggested that as-prepared sensors can be used for temperature sensing in microscopic subcellular biological environments.

Kumbhakar et al. (2021) synthesized Mn^{2+}-doped ZnS QDs (MZQDs) and used its reversible temperature-dependent PL emission quenching properties in the development of a smartphone-based optical thermometer. It was observed that temperature-dependent variations are present in PL intensity on using MZQDs in different forms, like powder form, aqueous dispersion, and polymer-encapsulated thin film. They have demonstrated a smartphone-based colorimetric imaging method for the measurement of temperature.

Yang et al. (2021a) synthesized N-GQDs with high blue fluorescence via a hydrothermal method using benzimidazoles as the precursor. It was reported that as-fabricated N-GQDs had a particle size of 3.8 nm with good water solubility, crystallinity, and photostability. It was observed that fluorescence of N-GQDs was quenched by tetracycline at elevated temperature and fluorescence intensity exhibited a linear reduction with temperature between 25°C and 100°C. They reported reversible and stable abilities of temperature sensing of as-prepared N-GQDs.

Sharma and Mehata (2022a) synthesized undoped as well as manganese-doped zinc selenide QDs in the temperature range of 77-300K. It was observed that intense blue and orange PL were exhibited by these as-prepared ZnSe and Mn@ZnSe QDs, respectively. It was found that PL intensity is dependent on temperature, decreasing with increasing temperature, and the maximum sensitivity values were 0.58% (225K) and 0.44%K^{-1} (250K) for ZnSe and Mn@ZnSe QDs, respectively.

13.3 Recent developments

Some recent developments in the use of QDs in fabricating different sensors have been summarized in Table 13.1.

TABLE 13.1 Recent advances in use of quantum dots in sensors.

Material	Application	Limit of detection	References
Carbon quantum dots	Detection of ammonia	10 nM	Ganesan et al. (2022)
Nitrogen-doped graphene quantum dots (N-GQDs) polyaniline (PANI)	Detection of ammonia	1500 ppm	Hakimi et al. (2018)
SnO_2 QDs	Detection of ammonia	–	Sahu et al. (2019)
Titanium dioxide quantum dots	Detection of hydrogen sulfide	500 ppb	Wu et al. (2022)
Graphene quantum dots	Detection of carbon dioxide	10–20 nm	Raeyani et al. (2020)
N-type nitrogen-doped carbon oxide quantum dots	Detection of humidity	20%–90%	Kondee et al. (2022)
Nitrogen-doped carbon quantum dots and red-emitting copper nanoclusters (CuNCs) complex	Detection of pesticide	7.49 and 3.03 nM	Chen et al. (2022)
Gold nanoparticles decorated quantum dots	Pesticide detection	Response range of 0.01–20 μM and limit of detection (LOD) of 7 nM	Jin et al. (2021)
MIP/$CsPbBr_3$ QDs	Detection of pesticide	0.10–500.0 μg L^{-1}	Zhang et al. (2022)
CdSe@CdS quantum dots	Detection of ochratoxin A	0.89 ng mL^{-1}	Jia et al. (2022)

(*Continued*)

TABLE 13.1 (Continued)

Material	Application	Limit of detection	References
ZnS/PbS core-shell quantum dots	Detection of hydrogen sulfide	300 ppm	Azimi and Rostami (2021)
Films of CdSe/ZnS core-shell type quantum dots	Detection of nitrogen dioxide	1–100 ppm	Ando et al. (2022)
PbS CQDs	Detection of nitrogen dioxide	–	Li et al. (2020)
Aptamer-modified quantum dots	Detection of *Staphylococcus aureus* in food and serum samples	2 CFU mL^{-1}	Tao et al. (2021)
CdSe/CdS/ZnS quantum dots	Detection of *Escherichia coli* and *P. Aeruginosa*	58 and 97 CFU mL^{-1}	Ye et al. (2022)
Tungsten trioxide quantum dots	Detection of *Listeria monocytogenes*	$1.3–1.3 \times 10^7$ CFU mL^{-1}	Zhu et al. (2021)
Carbon quantum dots	Detection of *E. coli* O157: H7 (*E. coli*)	487 CFU mL^{-1}	Hu et al. (2021) and Hong et al. (2021)
Fe_3O_4 nanoparticles and CdTe quantum dots	Detection of human serum albumin (HSA)	12 ng mL^{-1}	Liao et al. (2021)
S,N-CQDs	Detection of bendiocarb	0.02 μg mL^{-1}	Al Yahyai et al. (2021)
MoS_2 QDs and GQDs mixture (3:2)	Detection of cholesterol	35 nmol L^{-1}	Hassanzadeh and Khataee (2018)
3-Mercaptoproponic acid protected Mn@ZnSe QDs	Detection of Hg^{2+} and Pb^{2+} ions	Hg^{2+} and Pb^{2+} (0–100 μL)	Sharma and Mehata (2022b)
CdTe quantum dots	Thimerosal (TM), an organic mercury compound	26.6 μg L^{-1}	Tall et al. (2021)
CdZnTeS alloyed QDs	Detection of Pb^{2+} or Hg^{2+} ions	–	Hoang et al. (2022)

13.4 Conclusion

QDs are very sensitive toward any changes in chemical and biological environment, temperature, humidity, etc. Hence, these are successfully used for sensing the presence of certain chemicals. such as alcohol, liquefied petroleum gas, pesticides, drugs, hydrogen sulfide, ammonia. and many more, even if these are present in very low concentrations (ppm or even ppb level). The timely detection of any abnormality in body will help us in its immediate treatment. The leakage of toxic material can also be traced in time to have a safeguard. The list of sensors is not complete and it will continue increasing day by day.

14.1 Introduction

The whole world is facing scarcity of energy resources as presently available conventional fuels such as coal, kerosene, petrol, diesel, etc. will be reaching a point of complete exhaustion in the coming few decades. On the other hand, the demand for energy is increasing regularly, which cannot be fulfilled by the available resources, and therefore there is an urgent demand to find some alternate sources of energy, that are inexhaustible and/or renewable. Solar energy enters the scene here as it can fulfill the energy demands of society for many more centuries to come because it is abundantly available and free of cost. Hydrogen has a higher storage capacity than many other conventional fuels. There is a need for clean and eco-friendly energy sources as fossil fuel energy sources show adverse impacts on the environment also, whereas hydrogen is a clean energy source.

Hydrogen on combustion will produce water, which is a benign compound, and therefore it does not pollute our environment any more. Hydrogen has been very truly advocated as the fuel of the future and there is no doubt that it can fulfill the ever increasing requirement of energy and will replace the existing conventional fuels in the future. The use of hydrogen as a fuel for transportation and generation of electricity through fuel cells has been already established. Water covers almost three fourth of the Earth and if a method is developed to generate hydrogen gas from photosplitting of water, then it is welcome. Hydrogen produced from electrolysis of water is costly and does not help much because electricity is being used to decompose water. On the other hand, water is broken into hydrogen and oxygen by using solar energy as the source, which is freely and abundantly available.

There are still some existing challenges in this direction, which should be overcome in order to improve efficiency, durability, and lower the cost. These are:

- Enhance absorption of sunlight and better catalysis on surface.
- Developing highly active and eco-friendly photocatalyst.
- Stability and durability for a longer time may be improved using protective surface coatings.
- Photocatalyst may be modified so that the higher recombination rate of photogeneration electron−hole pairs is lowered or completely checked.
- The costs of production of hydrogen should be lowered by using low-cost photocatalysts through lowering their processing costs.
- Quantum dots (QDs) have come to our rescue at this stage as these QDs have certain unique properties, such as larger surface area (high surface to volume ratio), quantum confinement effect, and shifting absorption wavelength in visible and near infrared regions.

14.2 Hydrogen production

Hydrogen has the potential to be a dependable renewable source of energy that can replace fossil fuels in the current energy crisis, because of its zero emissions and its enhanced energy content (Dahiya et al., 2020). In the few last years, the interest in producers of hydrogen gas production has increased with the growing human activity, because it is considered as a main fuel of the future, which is clean energy as it does not liberate any carbon dioxide during its combustion. It is also economic and very flexible in various applications compared to traditional energy sources such as fossil fuel or nuclear plant (Nemzer et al., 2003; Bičáková and Straka, 2010; Melo and Silva, 2011). Hydrogen gas is regarded as one of the common forms of renewable energy resources. It is produced in various ways with different sources like hydrocarbons, alcohol, or water, such as photodehydrogenation of methanol (Ahmed et al., 2016), electrochemical photolysis of water (Carey and Oliver, 1976), photolysis, sonolysis, and sonophotolysis of water (Penconi et al., 2015), and electrolysis of different materials that contain water, and it is used in photovoltaic solar energy (Slama, 2013).

The hydrogen gas was first liberated from the splitting of the water molecule by Fujishima and Honda (1972). They used an electrochemical cell and observed the hydrogen gas evaluation at the TiO_2 electrode, when the TiO_2 electrode surface was irradiated by light, generating an exciton, that is, a photoelectron (e^-)−photohole (h^+) pair. There is a key role played by this photoelectron (e^-)−photohole (h^+) pair in the redox reaction. This reaction occurs on the TiO_2 electrode surface and the photoelectron produces a proton

from water. This electron also reduced a proton at the Pt electrode surface to afford hydrogen gas (Eqs. 14.1–14.4):

$$TiO_2 + 2\,hv \rightarrow 2\,e^- + 2\,h^+ \tag{14.1}$$

$$2\,e^- + H_2O \rightarrow \frac{1}{2}O_2 + 2\,H^+ \tag{14.2}$$

$$2\,e^- + 2\,H^+ \rightarrow H_2 \tag{14.3}$$

Therefore, the overall reaction is:

$$2\,hv + H_2O \rightarrow \frac{1}{2}O_2 + H_2 \tag{14.4}$$

Wrighton et al. (1976) evolved hydrogen gas using an electrochemical cell that contains a Pt electrode and a Sb-SnO_2 single-crystal electrode, which was irradiated with ultraviolet light in an alkaline solution. Bockris et al. (1985) reported the possible routes of hydrogen production from the decomposition of water, such as electrolysis, plasmolysis, magnetolysis, biocatalysis, thermal method, use of light photolysis or photocatalyst, radiolysis, etc. However, the maximum purity for hydrogen produced was found to be 99.99% using the electrolysis method because it is one of the best methods and it is also regarded as a green method. The normal electrolysis of water uses direct current in two steps (Eqs. 14.5–14.6):

$$2\,H_2O \rightarrow \frac{1}{2}O_2 + 2\,H^+ + 2\,e^- \text{ at } E^o = 1.229\ (1.23)\ V \tag{14.5}$$

$$2\,e^- + 2\,H^+ \rightarrow H_2 \text{ at } E^o = 0.00\ V \tag{14.6}$$

14.2.1 Basic principle of overall water splitting

Over the years, there have been several proposals for water splitting. In the late 1970s, major attempts were made at photocatalytic water splitting (Fujishima and Honda, 1972; Bard, 1979; Van Damme and Hall, 1979; Domen et al., 1980; Kudo et al., 1988). The powdered semiconductor photocatalyst will be useful for the large-scale use of solar water splitting due to its simplicity (Jia et al., 2014). TiO_2 has been one of the most extensively researched photocatalysts for water splitting (Ma et al., 2014). Through water splitting, photon energy is transformed to chemical energy, with a largely positive change in Gibbs free energy $\left(\Delta G^o = 237\ kJ^{-1}\ mol\right)$ (Han et al., 2017). When a light is incident on a photocatalyst with energy larger than the bandgap, then electrons in the valance band (VB) are excited into the conductive band (CB) leaving holes in the valence band (Cao et al., 2017).

As the first step in the photocatalytic process, both excited electrons and holes are generated; which subsequently diffuse to the surface of the

semiconductor particles independently (Vaiano et al., 2018). Protons play a major role in hydrogen generation. Photogenerated electrons and holes promote redox processes that are comparable to electrolysis. Total water splitting into H_2 (reduced by the electrons) and O_2 (oxidized by the holes) on the photocatalyst surface can be achieved (Eqs. 14.7 and 14.8 and Fig. 14.1) (Liu et al., 2015; Qiao et al., 2020; Marschall, 2021).

$$H_2O + 2\,h^+ \rightarrow 2\,H^+ + \frac{1}{2}O_2 \tag{14.7}$$

$$2\,H^+ + 2\,e^- \rightarrow H_2 \tag{14.8}$$

Overall water splits into H_2 and O_2 (Eq. 14.9).

$$H_2O \rightarrow \frac{1}{2}O_2 + H_2 \tag{14.9}$$

The bandgap width and potentials of the conduction and valence bands of a semiconductor photocatalyst material are important. The bottom level of the CB must be located at a more negative potential than H^+/H_2 (0 V at pH 0), whereas the VB must be more positive than the O_2/H_2O energy level (1.23 V vs NHE). This indicates that the minimum photon energy thermodynamically necessary to cause photocatalytic water splitting is 1.23 eV (Strataki et al., 2007; Kudo and Miseki, 2009; Hisatomi et al., 2014; Peng et al., 2019; Niu et al., 2021).

A photocatalyst must fulfill these three requirements (Maeda et al., 2005; Hisatomi et al., 2014):

- it should have a bandgap smaller than 3 eV;
- it has stability during the photocatalytic process, and
- its band edge potentials are adequate for overall water splitting.

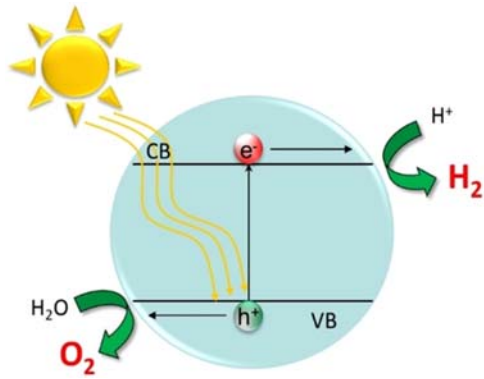

FIGURE 14.1 Schematic illustration of solar water splitting by using the photocatalyst. *Adapted from Marschall, R., 2021. 50 years of materials research for photocatalytic water splitting. Eur. J. Inorg. Chem. 2021(25), 2435–2441, with permission.*

The pure water splitting process exhibits a low efficiency because direct water splitting is still a difficult problem due to the inherent process drawbacks ($H_2 + O_2 = H_2O$) and it is a multistep process, in which four electrons are transferred. In addition, hydrogen is mostly created from fossil fuels such as natural gas, oil, and coal and only 2% is produced by water splitting (Miyoshi et al., 2018; Wang et al., 2018a; Fang et al., 2020; Dinda et al., 2020). Sacrificial reagents (as electron donors) are commonly used in water, such as alcohols (methanol, ethanol, and glycerol) to produce hydrogen efficiently by successfully scavenging photogenerated holes by suppressing back reaction, because O_2 is not evolved, and permitting a two-electron-transfer mechanism (Yang et al., 2013; Schneider and Bahnemann, 2013; Hisatomi et al., 2014).

Methanol is commonly employed as a sacrificial agent in photocatalysis for the evolution of H_2 from water under inert gas atmosphere, due to its strong reactivity, structural simplicity, and lack of C−C bonds (Cargnello et al., 2011). The water splitting reaction is a large uphill reaction with a ΔG° change. It is not an easy process compared to a reaction using a sacrificial agent (such as methanol), which is still an uphill reaction but less than that of water splitting. The energy change of sacrificial H_2 production is smaller than the energy change of water splitting. The use of sacrificial reagents leads to a significant decrease in ΔG° as it avoids the four-electron process of molecular oxygen formation. (Yasuda et al., 2018; Corredor et al., 2019) (Fig. 14.2).

Kawai and Sakata (1980) reported direct photocatalytic production of hydrogen from methanol and water over TiO_2-based catalysts, which produced H_2 and CO_2 from a mixture of H_2O/methanol (50:50 v/v %) after

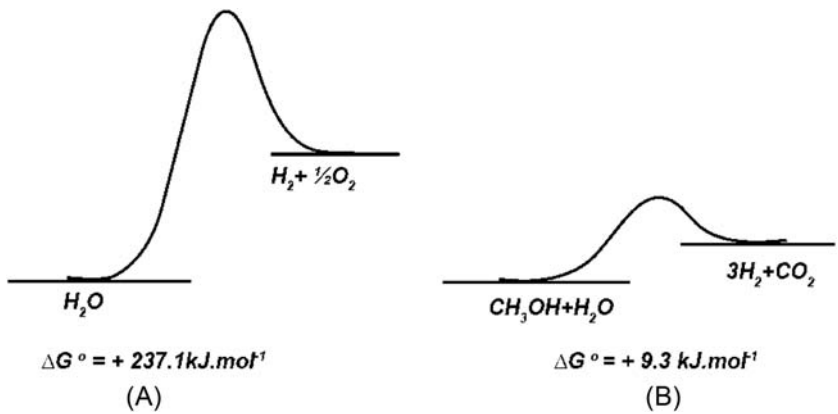

FIGURE 14.2 Comparison between H_2 production reaction: (A) from water splitting; and (B) from methanol. *Adapted from Yasuda, M., Matsumoto, T., Yamashita, T., 2018. Sacrificial hydrogen production over TiO_2-based photocatalysts: polyols, carboxylic acids, and saccharides. Renew. Sustain. Energy Rev. 81, 1627–1635, with permission.*

prolonged illumination. The absorption of photons from a light source with energy larger than the bandgap of the semiconductor photocatalyst promotes an electron from the VB of the semiconductor to the CB, generating an electron−hole pair. In this case, the photogenerated electrons are used to combine with protons in water to generate hydrogen (water reduction). The photogenerated holes are captured by sacrificial agents with a series of reactions (methanol oxidation) (Eqs. 14.10−14.14 and Fig. 14.3) (Wang et al., 2004; Puga, 2016; Huang et al., 2020; Zhao et al., 2020).

$$\text{Photocatalyst} \xrightarrow{hv} e^- + h^+ \tag{14.10}$$

$$CH_3OH + h^+ \rightarrow \cdot CH_2OH + H^+ \rightarrow HCHO + H \tag{14.11}$$

$$HCHO + H_2O + h^+ \rightarrow HCOOH + H_2 \tag{14.12}$$

$$HCOOH + h^+ \rightarrow CO_2 + H_2 \tag{14.13}$$

Overall process can be presented as Eq. (14.14).

$$CH_3OH + H_2O \xrightarrow{hv} CO_2 + 3H_2 \tag{14.14}$$

The reductive alkoxy radicals ($\bullet CH_2$-OH) are further oxidized to formaldehyde, formic acid, and carbon dioxide. The reductive alkoxy radicals $\bullet CH_2OH$ and $\bullet CO_2^-$ cannot react only with holes or hydroxyl radicals but also donate electrons to promote proton reduction to hydrogen, which is called the "doubling" effect. The same mechanisms are used for any other alcohol that carries a hydrogen atom on the carbon atom at the α-position of its OH group (Hainer et al., 2018). The by-products produced from methanol and other alcohols, such as formaldehyde, formic acid, and carbon dioxide, are also used as sacrificial agents for water splitting for hydrogen production

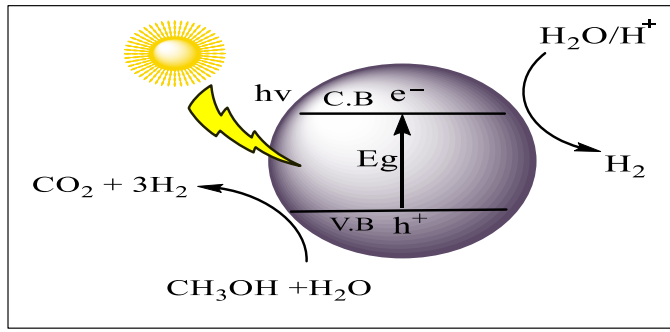

FIGURE 14.3 The photocatalytic hydrogen evolution process from aqueous methanol solution in the presence of inert gas (Kamat and Jin, 2018). *Adapted from Kamat, P.V., Jin, S., 2018. Semiconductor photocatalysis: tell us the complete story! ACS Energy Lett. 3, 622 − 623, with permission.*

(Bahruji et al., 2011; Coronado, 2013; Belhadj et al., 2017). The photocatalyst valence band potential has to be more positive than the sacrificial agent oxidation potential to oxidize such sacrificial agents (Luo et al., 2021).

Kumar et al. (2016) compared the activity for photocatalytic H_2 evolution under solar light irradiation in the presence of different scavengers. It was observed that hydrogen production was enhanced by using several organics such as ethylene glycol, because of the position of its oxidation potential with respect to the valence band potential of titania, and the generation of hydrogen was also found to be increased on increasing the polarity of alcohol. The photooxidation route of methanol depends on the molecular species adsorbed on the photocatalytic surface (Crampton et al., 2017). The carrier recombination rate was decreased after the traps of the hole by methanol on the catalytic surface; thus promoting the separation of electron−hole pairs (Chen et al., 2018).

Jitputti et al. (2008) have reported the photocatalytic evolution of H_2 from the water-splitting process using methanol as a sacrificial reagent in the presence of TiO_2 nanowires. The photogenerated holes or photogenerated oxygen are swiftly removed in an irreversible fashion, inhibiting mutual electron−hole recombination. Here, sacrificial reagents might compete with water in the reduction reaction. Fang et al. (2020) found that water was not the major source of hydrogen production in the photocatalytic process at Rh-loaded TiO_2 in the presence of sacrificial methanol at room temperature. It was found that the contribution of methanol decomposition ($\sim$60%) contributed even more than water splitting ($\sim$40%) because protons produced from both oxidation of methanol and ionization of water may be converted into hydrogen. In contrast, hydrogen generation was predominantly from water based on the combination of thermal and light energy over Rh-loading TiO_2.

Camacho et al. (2018) concluded that hydrogen production via water splitting is practically null compared to when methanol was added. It was revealed that the quantity of hydrogen produced increases with the increasing concentration of methanol. They could achieve the highest quantum efficiency under solar radiation of 7.7%. Gultom et al. (2017) reported that the highest activity could be achieved in 50% ethanol solution in the presence of ZnOS-10 with a hydrogen production rate of 14,800 $\mu mol\ g^{-1}\ h^{-1}$ and an apparent quantum yield (QY) of 31.5%. The QY and apparent quantum yield (AQY) are calculated by Eqs. (14.15 and 14.16), respectively, which define the stability and process efficiency of the photocatalytic system (Fukuzumi et al., 2018; Meng et al., 2020).

$$\text{QY}\ (\%) = \frac{\text{Number of reacted electrons}}{\text{Number of absorbed photons}} \times 100 \tag{14.15}$$

$$\text{AQY}\ (\%) = \frac{(\text{Number of photohydrogen molecules}) \times 2}{\text{Number of incident photons}} \times 100 \tag{14.16}$$

14.2.2 Photoelectrochemical cells

Photoelectrochemical (PEC) cells are one of the most efficient methods for converting solar energy into hydrogen (Landman et al., 2020). It was discovered that clean H_2 energy can be obtained by splitting water through a PEC cell using a TiO_2 photoanode. A typical PEC system consists of three electrodes:

- working electrode (photoanode);
- counter electrode (photocathode), for example, Pt or semiconductor, and
- reference electrode.

The typical PEC systems use photocatalysts [nanoparticles (NPs)] as photoelectrodes (such as TiO_2, ZnO, CdSe, CdS) (Gunasekaran et al., 2021). The electrodes are immersed in an aqueous electrolyte (Crespo-Quesada and Reisner, 2017). When a photoanode (semiconductor) comes in contact with an electrolyte, the Fermi energy level rises above the potential of electrocatalytic water splitting, which results in an upward band bending contact of a photocathode semiconductor with electrolyte. On the other hand, a downward band bending is present (Kibria et al., 2014; Guijarro et al., 2015). The difference in the electrochemical potential between the semiconductor electrode and the electrolyte causes a charge transfer process at the solid/liquid interface, resulting in an electric current flowing through the junction until an electronic equilibrium is reached (Jiang et al., 2017; Xiao and Liu, 2018).

The QDs having unique confined optical and electronic properties are applied to sensitize large bandgap photoanode materials (Zamiri and Bagheri, 2018). On irradiating the photoanode in the PEC cell, hydrogen is generated (Fig. 14.4) (Chen et al., 2016a).

They found that when photons are absorbed with an energy larger than their bandgap, the photoelectrons are excited and migrate into the unoccupied conduction band (CB) and holes are left in the valence band (VB) (exciton, i.e., electron−hole pairs generation). The exciton is separated by the built-in electric field, when photoexcited charge carriers have a longer lifetime and larger diffusion distance (Molaei, 2020), which leads to the higher process efficiencies due to easy separation and transport of the carriers (Xiao et al., 2019). Photoexcited electrons are swept toward the counter electrode through the back contact and an outside circuit, while the remaining holes participate in the oxidation reaction. In a PEC cell, electron−hole pairs produced by incident photons drive reduction−oxidation (redox) processes (Phang and Tan, 2019), in which holes oxidize the water/hole scavenger (HS) at the anode surface, while electrons travel to the counter electrode to reduce water and produce H_2 gas (Sahai et al., 2017).

The properties of the photoelectrode strongly influence the PEC efficiency of water splitting. An ideal photoelectrode should fulfill the following conditions:

- small bandgap for visible light absorption;

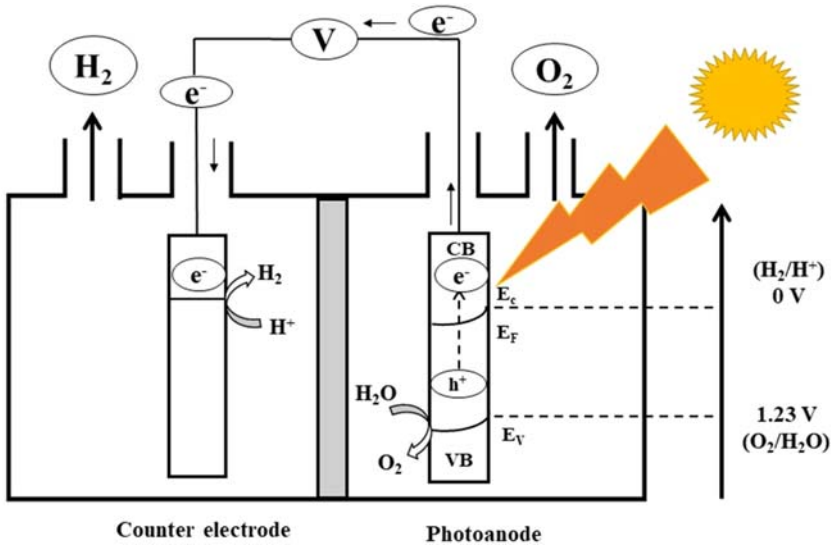

FIGURE 14.4 The basic principles of water splitting for a photoelectrochemical cell. E_F, Fermi level.

- photoelectrodes must be corrosion-resistant and chemically stable in aqueous solutions; under both conditions; dark and illumination;
- photogenerated charge separation ($e^- - h^+$) should be efficient; and
- the CB position of the semiconductor should be more negative than the (H^+/H_2) potential, and the VB should be more positive than the (O_2/H_2O) potential (1.23 V vs NHE) (Tamirat et al., 2016; Batubara and Zulys, 2019). It is shown in Fig. 14.5.

Semiconductor types, charge separation, transfer efficiency, crystal phases, and morphologies determine the efficiency for hydrogen production.

14.3 Metal-based quantum dots

14.3.1 Metals

Ye et al. (2012) prepared vertically oriented TiO_2 nanotube arrays (TNTAs) by a three-step electrochemical anodization technique. Then Pd QDs were prepared with uniform size and narrow size distribution on TiO_2 nanotubes by a modified hydrothermal method. It was reported that a high photocatalytic hydrogen production rate (592 $\mu mol\, h^{-1}\, cm^{-2}$) could be achieved with Pd@TNTAS. Chen et al. (2016b) prepared Ag QDs/g-C_3N_4 (Ag QDs/g-C_3N_4) photocatalysts via a novel one-step method using $AgNO_3$ and urea as precursors. As-composed Ag QDs with an average diameter of about 5 nm were found to be uniformly dispersed on the surface of g-C_3N_4 nanosheets.

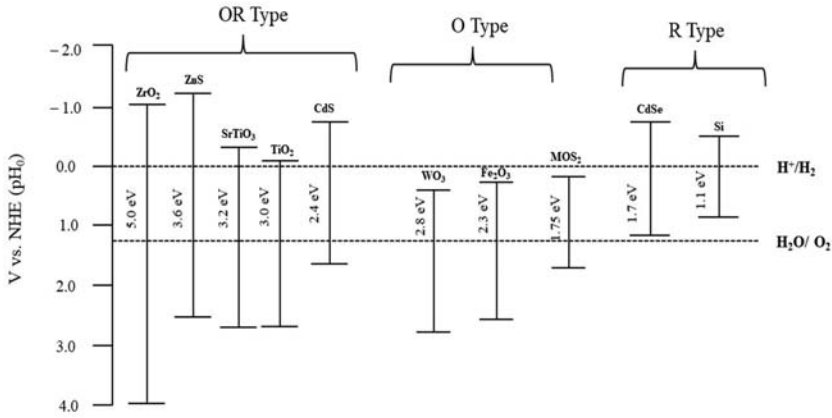

FIGURE 14.5 The band edge position and bandgaps for different semiconductors (OR, O, and R types). *OR*, oxidation and reduction; *O*, oxidation; *R*, reduction.

They used methanol as a sacrificial reagent. It was reported that as-prepared Ag QDs/g-C_3N_4 photocatalysts (0.5%) exhibited almost 4.6 times higher photoactivity for hydrogen production.

Kuang et al. (2016) embedded Au QDs in rimous cadmium sulfide nanospheres to synthesize hybrid photocatalyst via a simple hydrothermal process, which was followed by photoreduction. As rimous cadmium sulfide nanospheres had a rough surface and irregular fissures, these will strengthen their interaction and adhesion with Au QDs. It was revealed that the highest photocatalytic activity obtained for hydrogen generation was 601.2 $\mu mol\ h^{-1}\ g^{-1}$ by adjusting the Au loading. The synthesis of bimetallic (NiFe) quantum dot based electrocatalysts has been reported by Cirone et al. (2021). They optimized Ni:Fe ratio to tune QDs for increased electrochemical catalytic activity. The optimal compositions of these bimetallic QD based electrocatalysts was found to be 25.3% and 54.9% towards the hydrogen evolution reaction (HER) and oxygen evolution reaction (OER), respectively.

14.3.2 Oxides

Yang et al. (2009) have made use of N-doped ZnO concentrating on its PEC performance. The nitrogen has been commonly employed as a dopant to modify the electronic structures of metal oxide semiconductors as it resembles oxygen in size and low formation energy is required to replace oxygen (Zong et al., 2013). ZnO QDs dispersed in HS matrix were prepared by Xu et al. (2016). The HS contains S^{2-} and SO_3^{2-} groups. It was reported that as-synthesized ZnO QDs were hybridized with HS groups forming a stable ZnO QDs/HS hybrid hydrosol. This composite could produce H_2 with

a high rate of 260 μmol h^{-1} g^{-1}, which is almost 48-fold higher than for pure ZnO QDs.

Xie et al. (2017) decorated $BiVO_4$ QDs on the surface of screw-like SnO_2 nanostructures. They used the ionic layer absorption method for this purpose. It was revealed that the bandgap of $BiVO_4$ increases from 2.4 to 2.6 eV, when the particle size was decreased to about 5 nm. It was revealed that incident photon to current conversion efficiency was also increased up to 13.47%. It was reported that the rate of H_2 generation from splitting of water was 1.16 μmol h^{-1} cm^{-2} over $BiVO_4$ quantum dot/screw-like SnO_2 nanostructures in the presence of visible light. Liu et al. (2018) reported the synthesis of Co_3O_4 QDs TiO_2 nanobelts (NBs) hybrids via a facile hydrothermal method. They could obtain simultaneous production of H_2 and O_2 from pure water in the presence of light with high evolution rates of 22.0 and 41.8 μmol h^{-1} g^{-1}, respectively. It was observed that these production rates were higher compared to Co_3O_4 and TiO_2 NBs. The size of Co_3O_4 QDs was found to be ~3 nm, which not only improved the light sensitivity but also promoted the transfer of electrons from TiO_2 to Co_3O_4 QDs and as a result, H_2 generation was also enhanced.

Qian et al. (2018) reported the synthesis of p-type CuO/n-type CeO_2 heterojunction in situ grown on graphene. It was revealed that the H_2 evolution rate of the CeO_2−CuO QDs/graphene could reach 2481 μmol h^{-1} g^{-1} and remained unaffected for four consecutive hydrogen production cycles. The protonated graphitic carbon nitride (p-C_3N_4) loaded with IrO_2 QDs was fabricated by Wang and Li (2018) via a hydrothermal approach. It was found that IrO_2 QDs had an average diameter of approx 2 nm and these were highly dispersed and anchored on surfaces of p-C_3N_4. It was reported that as-prepared IrO_2/C_3N_4−0.6 wt.% photocatalyst could produce hydrogen and oxygen at a rate of 45 and 20 μmol h^{-1}, respectively.

Zhang et al. (2018a) constructed novel SnO_2 QDs modified TiO_2 nanorod arrays (NAs) by calcining $SnCl_2$-adsorbed on TiO_2 NAs. It was reported that photocurrent density of SnO_2 QDs/TiO_2 NAs was five times higher than that obtained with only TiO_2 NAs. It was also revealed that SnO_2 QDs/TiO_2 NAs exhibited a high photoelectrocatalytic activity for overall water splitting affording O_2 and H_2 at the rate of 11.87 and 27.85 μmol cm^{-2} h^{-1}, respectively. Such an excellent performance of water splitting may be due to its Z-scheme heterostructure. They also developed an effective strategy by distributing $BiVO_4$ QDs on nano tin oxide (Zhang et al., 2018a,b). They also used carbon QDs (CQDs) to enhance charge transfer and electrocatalytic properties at the $BiVO_4$-SnO_2 interface. It was observed that this composite afforded a hydrogen generation rate of 0.54 μmol h^{-1} without using any bias.

The dodecahedral nitrogen-doped carbon-coated CuO-In_2O_3 p−n heterojunction (DNCPH) was fabricated by Sun et al. (2019). As-prepared composite exhibited an excellent photocatalytic production efficiency of H_2. It was

revealed that improved separation efficiency of excitons (photogenerated electron/hole pairs) and coated N-doped C layer with CuO-In_2O_3 p−n heterojunction was responsible for enhanced photocatalytic hydrogen production efficiency of DNCPH. Reddy et al. (2020) prepared functionalized carbon nanotubes−titania QDs (FCNT-TQDs) and used them as photocatalysts in the presence of sunlight for hydrogen production. It was reported that the photocatalyst synthesized may be tuned by the addition of copper to achieve a highest hydrogen production rate up to 54.4 mmol $h^{-1}g^{-1}$, which was about 5.4 and 25 times higher than that obtained on using FCNT-TQDs composite and pristine TiO_2 QDs, respectively.

14.3.3 Metal sulfides

Although bulk CdSe produces H_2 from water under visible light irradiation, CdSe-nanoribbons were able to generate hydrogen from aqueous sodium sulfite/sulfide solution with a quantum efficiency (9.2%) at 440 nm (Frame and Osterloh, 2010). It was observed that ultrasonication and exfoliation of bulk MoS_2 can produce MoS_2 nanoplates. When the CdSe nanoribbons are chemically linked to these nanoplates, the activity was found to increase about four times. CdS quantum dot coupled graphitic carbon nitride photocatalysts were synthesized by Ge et al. (2012) through chemical impregnation. The effect of CdS content was observed on the rate of photocatalytic hydrogen evolution under visible light irradiation using platinum as a cocatalyst in aqueous solutions of methanol. It was revealed that the optimal CdS QD content was 30 wt.%, where H_2 evolution rate could reach 17.27 μmol h^{-1} in the presence of visible light, and it was about nine times more than that with pure g-C_3N_4.

The oil refineries are venting off almost 15%−20% H_2S and hardly 5% of it is utilized to produce sulfur and water. Apte et al. (2012) investigated a novel Q-CdS (highly monodispersed) germanate glass nanocomposite. The size of CdS QDs varied between 4−14 nm. A high rate of evolution of H_2 (3780 μmol h^{-1}) was obtained. It was also observed that as-prepared catalyst was stable and it can be also regenerated easily as compared to other catalysts. This glass nanocomposite also exhibited rapid methylene blue degradation in the presence of visible light. It was suggested that such orthorhombic QD−CdS−glass nanocomposites can find potential applications in LED, solar cells, and other optoelectronic devices.

Cao et al. (2013) grew well dispersed CdS QDs on g-C_3N_4 nanosheets via a solvothermal method. They used dimethyl sulfoxide. It was observed that as-prepared CdS−C_3N_4 nanocomposites exhibited an excellent efficiency for photocatalytic hydrogen evolution in the presence of visible light as compared to pure g-C_3N_4. It was revealed that composite with 2 wt.% CdS showed a higher hydrogen evolution rate (4.494 mmol h^{-1} g^{-1}), which is about 115 times more than that obtained with pure g-C_3N_4. Schweinberger et al. (2013)

synthesized Pt clusters of various sizes and embedded these on CdS quantum rods. They reported that the size of the Pt cluster had a significant impact on photocatalytic effectiveness. The highest efficiency could be achieved by a Pt cluster comprising Pt_{46}.

Li et al. (2014) decorated $ZnIn_2S_4$ microspheres (ZIS MSs) with CQDs as well as platinum NPs (dual cocatalysts). It was observed that ZIS MSs coloaded with Pt and CQDs exhibited a high photocatalytic production rate of H_2 of 1032.2 $\mu mol\ h^{-1}\ g^{-1}$ in triethanolamine aqueous solution in the presence of visible light, which was much higher compared to pure ZIS, CQDs-decorated ZIS, and Pt-loaded ZIS. The CdS QDs supported on two oxides (Ga_2O_3 and In_2O_3) were prepared by Pan et al. (2014) and used for the evolution of H_2 from aqueous solutions containing lactic acid under visible light. It was observed that H_2 evolution rates on CdS/Pt/In_2O_3 and CdS/Pt/Ga_2O_3 were 1032.2 and 995.8 $\mu mol\ h^{-1}$, respectively. These rates of H_2 evaluation were much higher compared to Pt/CdS (108.09 $\mu mol\ h^{-1}$), Pt/In_2O_3 (0.05 $\mu mol\ h^{-1}$), and Pt/Ga_2O_3 (0.12 $\mu mol\ h^{-1}$). It was suggested that the surface properties of the metal oxides played two important roles:

- anchoring of CdS QDs and Pt NPs; and
- efficient trapping of photogenerated electrons.

Wang et al. (2014) reported a photocatalyst, nickel-hybrid CdS QDs (Ni_h-CdS QDs), which was prepared in situ from nickel salts and CdS QDs. They used 3-mercaptopropionic acid as a stabilizer. It was found that 403.2 μmol of H_2 was obtained with a high evolution rate of 74.6 $\mu mol\ h^{-1}\ mg^{-1}$ under visible light irradiation for 20 h as compared to MPA-CdS QDs (mercaptopropionic-acid-stabilized CdS QDs). Cu_2S QDs coupled three-dimensional flower-like hierarchical BiOBr (Cu_2S QDs/BiOBr) were prepared by Wang et al. (2015) via a precipitation method. It was observed that Cu_2S QDs had an average diameter of 10 nm and these were uniformly attached on the surface of BiOBr. It was reported that as-prepared Cu_2SQDs/BiOBr composite exhibited higher water splitting and they could obtain 717 $\mu mol\ g^{-1}$ of H_2 with 3 wt.% Cu_2SQDs/BiOBr containing 1 wt.% Pt. This rate was about 3.1 times higher as compared to only Cu_2S NPs.

Yue et al. (2016) synthesized CdTe/CdS QDs using sulfur tolerant $[Mo_3S_{13}]^{2-}$ nanoclusters, which exhibited much better photocorrosion resistance than regular CdTe QDs for photocatalytic hydrogen generation. The sulfur compound covered CdTe/CdS QDs. It was observed that as-prepared composite exhibited higher visible light photocatalytic H_2 generation compared to CdTe QDs with cocatalyst Pt. A novel CdS/ZnO heterojunction was fabricated by Ma et al. (2017), which is composed of zero-dimensional CdS QDs and two-dimensional ZnO nanosheets (NSs). It was reported that as-obtained CdS/ZnO 0D/2D heterostructures exhibited excellent photocatalytic activity for the evolution of hydrogen from water splitting in comparison

with other CdS/ZnO heterostructures with different combinations (0D/3D, 2D/2D, and 3D/0D). It was observed that out of these, CdS/ZnO-12 (12 deposition cycles of CdS QDs) exhibited the highest evolution rate of hydrogen of 22.12 mmol g^{-1} h^{-1}, which was about 13 and 138 times higher than produced with single CdS (1.68 mmol g^{-1} h^{-1}) and ZnO (0.16 mmol g^{-1} h^{-1}), respectively. It was revealed that as-prepared CdS/ZnO-12 exhibited excellent stability without any significant loss for five cycles in 25 h.

A vertical self-assembly of ultrathin $CdIn_2S_4$ nanosheet arrays on the reduced graphene oxide (rGO) has been prepared by Xue et al. (2017) via a facile hydrothermal method. Here, ZnS QDs were in situ deposited on $CdIn_2S_4$ nanosheet arrays. It was reported that as-prepared 3D nanosheet arrays architecture with GO (13 wt.%) exhibited the optimum, highest hydrogen generation of 6.82 mmol g^{-1} h^{-1} corresponding to the photocurrent transient response (107.4 μA cm^{-2}). An inverse structure of $Cd_{0.5}Zn_{0.5}S$ QDs was reported by Zhou et al. (2017) loaded onto the onion-like carbon (OLC) matrix. It was observed that as-prepared $Cd_{0.5}Zn_{0.5}S$ QDs with average diameter of 6.9 nm were uniformly distributed on an OLC (30 nm) matrix. An optimum rate of H_2 generation, 58.6 and 2018 μmol h^{-1} g^{-1}, could be achieved on irradiation of visible light and 58.6 μmol h^{-1} g^{-1} under the irradiation of (550−900 nm), respectively using $Cd_{0.5}Zn_{0.5}S$/OLC composite samples. Such a reverse construction using hydrogen has a great potential for noble metal-free solar production of hydrogen.

Kitazono et al. (2017) photodeposited CdSe on a CdS-preloaded mesoporous TiO_2 nanocrystalline film. As a result, CdS(core)−CdSe(shell) QDs (CdS@CdSe/mp-TiO_2) were obtained with a heteroepitaxial nanojunction. They fabricated quantum-dot-sensitized PEC (QD-SPEC) cells with photoanode | 0.25 M Na_2S, 0.35 M Na_2SO_3 (in water)| cathode. It was observed that a CdS@CdSe QD-SPEC cell could achieve solar-to-current efficiency (STCE) of 0.03% under simulated sunlight (AM 1.5, one sol). An increase in STCE up to 0.048 was obtained on application of 0.1 V between the electrodes, far surpassing the CdSe/mp-TiO_2 and CdS/mp-TiO_2 photoanode cells. A WS_2/graphitic carbon nitride (CN) (2D/2D) nanosheet heterostructure was decorated with CdS QDs by Zou et al. (2018). It was observed that optimized CdS/WS_2/CN exhibited an excellent photocatalytic H_2 evolution rate of 1174.5 μmol h^{-1} g^{-1} without using any cocatalyst, which was about 67 times higher than for pure CN nanosheets. It was also revealed that CdS/WS_2/CN photocatalyst showed excellent stability as well as reusability without any significant loss role in photocatalytic H_2 evolution within four cycles in 20 h.

Hao et al. (2018) synthesized Bi_2WO_6 QDs decorated g-C_3N_4 nanoplates through a one-step hydrothermal method. The size of Bi_2WO_6 QDs was found to be about 3.5 nm. It was reported that a Bi_2WO_6 QDs/g-C_3N_4 Z-scheme not only increased the separation efficiency of charge, but it also enhanced the ability of PEC water splitting. Thick-shell CdSe/$CdSe_xS_{1-x}$/CdS QDs were synthesized by Zhao et al. (2018) with a pyramidal shape.

It was reported that these exhibited a QY of ~15%. As-prepared pyramidal QDs were then applied as light absorbers in a PEC system, leading to a saturated photocurrent density of ~12 mA cm^{-2}, which could provide an H_2 generation rate of 90 mL cm^{-2} day^{-1}.

Wang et al. (2018b) decorated TiO_2 nanotube arrays (TiO_2 NTAs) with MoS_2 QDs by an electrodeposition method. It was reported that as-prepared MoS_2 QDs/TiO_2 NTAs exhibited an increased photocatalytic activity compared to pristine TiO_2 NTAs for H_2 evolution in the presence of sunlight. They did not use any sacrificial agents or cocatalysts. The optimal H_2 evolution rates were observed to be 31.36, 5.29, and 1.67 μmol cm^{-2} h^{-1} in the presence of UV, visible, and near-infrared illumination, respectively. Such an enhanced photocatalytic activity may be due to decreased bandgap energy and surface plasmonic properties, which increased absorption capacity for visible and near-infrared light. Xue et al. (2018) fabricated high-density NiS_x QDs as a highly efficient cocatalyst on the surface of $Cd_{0.8}Zn_{0.2}S$/rGO nanosheet composites. It was reported that a two-dimensional (2D) $Cd_{0.8}Zn_{0.2}S$/rGO nanohybrid system with 2 wt.% NiSx loading could achieve H_2 evolution rate of 7.84 mmol g^{-1} h^{-1} under visible light irradiation, which is almost 1.4 times higher as compared to Pt/$Cd_{0.8}Zn_{0.2}S$/rGO.

The Se-doped CdS QDs with different Se doping levels were prepared via a solvothermal procedure (Shi et al., 2019). It was reported that photocatalytic performance of as-prepared $CdS_{0.9}Se_{0.1}$ QDs (without any cocatalysts) was enhanced to give a hydrogen evolution rate of 29.12 mmol h^{-1} g^{-1} under simulated solar irradiation, which was about 23.5 times higher as compared to CdS QDs. Yang et al. (2019) prepared a series of Zn−$AgIn_5S_8$/g-C_3N_4 (0D/2D) nanocomposites by growth (in situ) of the Zn−$AgIn_5S_8$ QDs (QDs) on g-C_3N_4 nanosheets. It was reported that the hydrogen production rate with Zn−$AgIn_5S_8$/g-C_3N_4 nanocomposites was found to be optimum, when the mass ratio of g-C_3N_4 was kept at 10%, which was 1.39, about 138.6 times higher than pure Zn−$AgIn_5S_8$ QDs and g-C_3N_4, respectively. It was also revealed that as-prepared Zn−$AgIn_5S_8$/g-C_3N_4 nanocomposites exhibited good cycle stability.

Yu et al. (2019) used Ag_2S QDs as both photocatalysts and electrocatalysts. It was observed that H_2 production rate could reach 858 μmol h^{-1} g_{catal}^{-1} under 100 mW cm^{-2}. Zheng et al. (2019) synthesized a p-n heterojunction photocatalyst for splitting of water. They incorporated p-type $CuInS_2$ QDs into n-type polymeric carbon nitride (CN) via a self-assembly and calcination method. It was reported that hydrogen evolution rate of $CuInS_2$/CN hybrid was two-fold more than that with pristine CN. A metal−organic framework (MOF)-derived synthesis was reported by Shi et al. (2020). They could obtain a controlled mixed-phase (rutile and anatase) of TiO_2 NPs, retaining MOF crystal morphology. It was observed that MOF-derived TiO_2 film, which was sensitized by core−shell CdSe@CdS QDs, exhibited an higher PEC device stability of +42.1% with PEC performance as +47.6%. It was suggested that

this protocol can improve the efficiency of the PEC system based on TiO_2-QDs heterojunction for hydrogen generation.

Chen et al. (2019) prepared ZnCdS QDs. It was reported that the photocatalytic H_2 production activity of as-prepared QDs can be optimized by adjusting their quantum sizes. It was revealed that maximum H_2 production rate of 3.70 mmol h^{-1} g^{-1} could be obtained with it, without using noble metal cocatalysts in the presence of visible light, which was much better than that of ZnCdS and ZnCdS-based catalysts. Miodyńska et al. (2020) increased the photoactivity of urchin-like rutile particles by decorating these with pristine as well as Er- or Yb-doped Bi_2S_3 QDs. They varied doping degrees (1−15 mol%), and QDs loadings (1−20 wt.%), and the best hydrogen evolution performance could be achieved with Er and Yb contents of 10 mol%. It was observed that hydrogen productivity of 1576.7 μmol g_{cat}^{-1} could be achieved for TiO_2 decorated by 10 mol% Yb-doped Bi_2S_3 QDs after 20 h irradiation. Su et al. (2020) reported that nickel in zinc blende cadmium−zinc sulfide QDs is an efficient and stable photocatalyst for splitting of water under sunlight. It was observed that finely tuned Ni atoms dispersed in these QDs exhibited H_2 production activity of 18.87 mmol h^{-1} g^{-1}.

14.3.4 Others

Chen et al. (2010) studied the utilization of CdTe quantum-dot-sensitized ZnO:nanowire arrays for water splitting. It was reported that photocurrent and stability was significantly improved. It was also revealed that the addition of nitrogen alters the electronic state, which improves the ability for water splitting. CoP QDs embedded in S,N-codoped graphite carbon (CoP@SNC) were reported by Meng et al. (2018). They used organophosphoric acid as a precursor of both phosphorus and carbon. Benefiting from the strong coupling and synergistic effect between CoP QDs and highly conductive S,N-codoped carbon, well-structured porosity and high specific surface area. It was observed that as-synthesized CoP@SNC exhibited excellent activities for HER, OER, and oxygen reduction reaction (ORR). It acts as a trifunctional electrocatalyst for overall splitting of water.

Zhu et al. (2018) loaded black phosphorus QDs (BP QDs) on MXene nanosheets. It was revealed that as-prepared BP QDs/MXene nanohybrids can serve as a bifunctional electrocatalyst in producing both hydrogen and oxygen. It was observed that a current density of 10 mA cm^{-2} was reached at a potential of only 1.78 V on using BP QDs/MXene nanohybrids cathode and anode in a full cell for overall water splitting. A composite consisting of CdSe QDs and indium-doped $BaTiO_3$ was synthesized by Zhong et al. (2019). The optimal load ratio of CdSe QDs with 2.5% indium (7.5 mol.%) was found to increase the production of hydrogen (0.437 mmol g^{-1} h^{-1}) as compared to undoped composite (0.258 mmol g^{-1} h^{-1}).

The $BiVO_4@ZnIn_2S_4/Ti_3C_2$ MXene QDs assembly (photocatalyst) was fabricated by Du et al. (2020). It was observed that $BiVO_4@ZnIn_2S_4/Ti_3C_2$ MXene QDs could achieve effective splitting of water into H_2 and O_2 in the presence of visible light with rates of 102.67 and 50.83 $\mu mol\ g^{-1}\ h^{-1}$, respectively. Yan and Jin (2021) derived NiP_2 QDs (n-type) in situ from the three-dimensional nanoflower NiAl-LDH. They also constructed n-type p-n heterojunction by coupling NiP_2 QDs and Cu_3P NPs (p-type) for hydrogen generation.

14.4 Carbon and graphene-based quantum dots

Yu et al. (2013) used an impregnation method to prepare graphene quantum dots (GQDs) anchored inside inversely structured TiO_2 nanotubes-array (TiO_2-NA) and CdS-modified TiO_2 nanotubes-array (CdS/TiO_2-NA). It was observed that the hydrogen evolution rate was greatly increased on loading GQDs into TiO_2-NA and CdS/TiO_2-NA. It was revealed that the light-filtering effect of graphene was inhibited as compared to graphene sheets, when graphene is broken into GQDs. However, the morphology of TiO_2 the nanotube array was still maintained even when anchoring GQDs inside, which favored mass transfer.

Nitrogen-doped graphene oxide QDs were prepared by Yeh et al. (2014). As-prepared catalyst samples exhibited both p- and n-type conductivities and overall water-splitting under visible light. It was reported that QDs contain p-n type photochemical diodes and active sites for O_2 and H_2 evolution were n- and p-domains, respectively. It was also revealed that this reaction mimics biological photosynthesis. Martindale et al. (2015) produced CQDs, as a homogeneous photocatalytic system with a Ni-bis(diphosphine) catalyst. It was observed that it could produce hydrogen at a rate of 398 $\mu mol\ (g_{CQD})^{-1}\ h^{-1}$. It was revealed that these CQDs exhibited activity in the visible region and maintained their photocatalytic activity for a day. Qu et al. (2015) prepared S,N-GQDs by doping GQDs with heteroatoms (S, N). It might be utilized as a sensitizer in photocatalytic processes. It was observed that loading of S,N-GQDs onto TiO_2 nanocrystals resulted in the generation of H_2 through splitting of water. They revealed that the H_2 generation rate was about 4.3 $mol\ h^{-1}$ under visible light.

CQDs were deposited by Li et al. (2016) onto graphite-like carbon nitride nanosheets (CNNS) to afford CNNS/CQDs composites. It was found that as-prepared CNNS/CQDs composites exhibited a much higher photocatalytic hydrogen production rate (116.1 $\mu mol\ h^{-1}$) under visible light irradiation, which was almost three times higher than with pure CNNS (37.8 $\mu mol\ h^{-1}$). The photoanodes were fabricated by Shi et al. (2016) consisting of WO_3 nanoflakes decorated with CQDs via seed-mediated solvothermal method and impregnation-assembling. It was revealed that the photocurrent density of 1.46 $mA\ cm^{-2}$ at 1.0 V versus Ag/AgCl could be achieved for CQDs/

WO_3 electrode, which was almost more than double as compared to only the WO_3 electrode. Such an enhancement was due to the increased light harvesting ability of CQDs and rapid charge transfer across the interface between the electrolyte and CQDs/WO_3 electrode.

Sulfur-doped graphene oxide QDs (S-GOQDs) were synthesized by Gliniak et al. (2017). They observed efficient photocatalytic hydrogen generation under direct sunlight irradiation. The doping of S atoms into the GOQDs was confirmed. They could achieve an initial rate of 18,166 and 30,519 $\mu mol\ h^{-1}\ g^{-1}$ in pure water and in 80% ethanol aqueous solution, respectively. Yan et al. (2017) prepared nitrogen-doped graphene QDs (NGQDs)-$ZnNb_2O_6$/g-C_3N_4 heterostructures and used them as hydrogen evolving catalysts. It was reported that as-prepared NGQDs-$ZnNb_2O_6$/g-C_3N_4 heterostructures could achieve a higher hydrogen evolution rate of 340.9 $\mu mol\ h^{-1}\ g^{-1}$, when the mole ratio Zn/gC_3N_4 and NGQDs were kept at 1:7 and 5%, respectively.

Pan et al. (2018) prepared CQDs modified porous g-C_3N_4/TiO_2 two-dimensional (2D) nanoheterojunctions. The TiO_2 NPs were introduced via a hydrothermal method while CQDs were successively introduced on the surface of the porous g-C_3N_4 and TiO_2 by coupling. It was observed that hydrogen production using these 2D nanoheterojunctions was almost double that obtained with unmodified samples. The cobalt carbide (Co_2C) was prepared by Guo et al. (2018). A combination of colloidal QDs/Co_2C can produce hydrogen at the rate of $\sim$18,000 $\mu mol\ g^{-1}\ h^{-1}$, which was about 10 times more than that of bare QDs under similar conditions.

Wang and Li (2018) and Wang et al. (2018a,b) reported that the coloading of graphene QDs and PdS on ZnCdS surface as cocatalysts can increase the efficiency of photocatalytic evolution of H_2 in the presence of visible light. This photocatalyst (GQDs/ZnCdS/PdS) was prepared by two steps: (1) hydrothermal coupling of GQDs on ZnCdS surface, and (2) an in situ chemical deposition of PdS. It was reported that as-prepared GQDs/ZnCdS/PdS exhibited an H_2 evolution rate of 517 $\mu mol\ h^{-1}$, which is about 15, 1.7, and 7 times higher as compared to ZnCdS, ZnCdS/PdS, and GQDs/ZnCdS respectively. This photocatalyst has a good stability. Enhancement of photocatalytic activity was attributed to coloading of the GQDs (reduction) and PdS (oxidation) as respective cocatalysts.

A facile method has been reported by Liu et al. (2019) to prepare efficient and robust Ru-M (M = Mn, Ni, Cu) bimetallic NPs and carbon quantum dot hybrid (RuM/CQDs). It was observed that RuNi/CQDs catalysts exhibited an excellent HER performance in all pH ranges. It was revealed that Ni doping resulted in a weakening of the hydrogen bonding energy of close surface Ru atoms, which played an important role in enhancing the HER activity. Zhang et al. (2019) reported that a dendrite-like plasmonic bimetal (CuNi) can be used as a photocatalyst, which is nonsemiconducting in nature. It produced electrons for photocatalytic splitting of water to

generate hydrogen, but when such a bimetal is supported by a catalyst like CQDs, then the photocatalytic water splitting rate was found to be highest at 55.19 μmol g^{-1} h^{-1}. The content of CQDs in the photocatalyst was kept at 3 wt.% for optimum conditions. It was reported that this photocatalyst was stable for four cycles over 20 h.

The B-doped g-C_3N_4 QDs (BCNQDs) were prepared by Wang et al. (2013) via a facile molten salt method. They used melamine and boron oxide as the precursors. The BCNQDs were introduced onto the surface of g-C_3N_4, via hydrothermal treatment and as a result a g-C_3N_4/BCNQDs heterojunction was constructed. As-prepared g-C_3N_4/BCNQDs heterojunction exhibited excellent hydrogen evolution performance for water splitting in the presence of visible light irradiation. *Bombyx mori* silk, a natural nitrogen-rich biopolymer protein, is earth-abundant and sustainable. Wang et al. (2020) derived nitrogen-doped CQDs (N-CQDs) from *Bombyx mori* silk fibroin and then immobilized them onto TiO_2 nanotube arrays (TiO_2 NTAs) using a hydrothermal approach. As-prepared N-CQDs decorated TiO_2 NTA heterostructures (N-CQDs@TiO_2 NTAs) could split water into H_2 and O_2 with production rates of 30.12 and 14.96 μmol cm^{-2} h^{-1}, respectively.

Liu et al. (2020) prepared N-doped CQDs (NCDs) modified defect-rich g-C_3N_4 (DCN) via an impregnation method. It was revealed that optimized NCDs/DCN exhibited excellent photocatalytic H_2 production with an evolution rate of 3.68 μmol h^{-1} g^{-1}. Nasir et al. (2020) prepared a 1D nanofiber of TiO_2 via electrospinning. Then they produced a needle-like structure on this fiber through an alkali hydrothermal method and chemical vapor deposition method. The g-C_3N_4 QDs and nanoflakes of $SnSe_2$ fiber (branched) were loaded on TiO_2 via a heterojunction. It was observed that the composite exhibited excellent photocatalytic performance for the production of hydrogen (2375 μmol g^{-1} h^{-1}) with quantum efficiency of HER (>16%).

Nitrogen-doped graphene QDs (N-GQDs) were synthesized by Tsai et al. (2020) via a hydrothermal cutting approach. The concentration of nitrogen was controlled with a change in concentration of nitrogen source urea. It was revealed that N-GQDs prepared by using 2 g of urea gave the highest photocurrent. They also observed that photocatalytic activity of 2N-GQDs (photocatalyst) for production of hydrogen was higher compared to pristine GQDs. Raza Naqvi et al. (2020) developed a nitrogen-doped carbon dots (NDCDs)-AgNi alloy. Then, it was used as an electrocatalyst for electrochemical water splitting. NDCDs-AgNi alloy NPs were synthesized by easy and scalable methods. NDCDs were prepared by the pyrolysis of ethanolamine. It acted as a good electrocatalyst for HER. It was also revealed that as-prepared NDCDs-AgNi alloy also exhibited superior OER activity.

Roy et al. (2020) demonstrated that chlorophyll(*a*)/CQDs (Chl/CQDs) bionanocomposite (b-NC)-decorated Si-nanowires (SiNWs) can surpass the efficiency for PEC generation of hydrogen. It was revealed that efficiency reaches ~7.86%, which is highest reported so far with hybrid Si-based

photocathodes. They measured the hydrogen evolution rate to be $\sim 113\ \mu mol\ h^{-1}$ at 0.8 V versus RHE under 1 sol illumination. Duan et al. (2021) developed a simple exfoliation−sonication approach to prepare nitrogen carbide QDs (CNQDs)-doped nitrogen carbide nanosheet (CNS) composite, which can be used as a photocatalyst to produce hydrogen in the presence of organic pollutants such as acridine orange, or aniline. In their presence, it was observed that hydrogen evolution efficiency was increased from 8.8 to 11.7 and 32.1 $mmol\ g^{-1}\ h^{-1}$ in the presence of aniline and acridine orange, respectively. It was revealed that heterojunction of CNQDs/CNS induced the separation of photogenerated electron−hole pairs, where electrons will migrate to CNQDs transforming protons into hydrogen molecules, and holes migrated to CNS, oxidizing organic pollutants, simultaneously.

Elsayed et al. (2021) have prepared N-doped carbon QDs (NCQDs) into polymer dots resulting in significant enhancement in their photocatalytic performance as well stability. The role of NCQDs was suggested to enhance the charge separation and the photocatalytic efficiency of the polymer dot. It was reported that NCQDs were easily introduced into the polymer dot, and as a result the hydrogen evolution rate was increased by about five times as compared to pure polymer dots.

Liang et al. (2021) prepared nitrogen doped graphene quantum dots as a photocatalyst dodecahedron nano-Au particles. It was revealed that as-obtained graphene@Au catalysts exhibited an efficient photocatalytic overall water splitting involving both; high valuable H_2O_2 and clean H_2 energy with generation rate as 49.7 and 65.6 $\mu mol\ g^{-1}\ h^{-1}$, respectively. The separation of hydrogen peroxide from hydrogen gas is easy as compared with most water splitting method that liberated hydrogen gas and oxygen gas, which further needs gas separation.

Nitrogen-doped graphene QDs (NGQDs) were prepared by Liu et al. (2021) and then used as a cocatalyst of $SrTiO_3(Al)/CoO_x$ for photocatalytic overall water splitting to generate hydrogen. It was found that as-prepared $NGQDs/SrTiO_3(Al)/CoO_x$ was highly active for splitting of water with an evolution rate of H_2 and O_2 as 18.8 and 9.0 $\mu mol\ h^{-1}$, respectively. Wu et al. (2021) synthesized an organic semiconductor (DAnTMS compound) using trimethylsilylacetylene (TMS) and 9,10-dibromoanthracene (DAn). Then, they designed a metal-free composite photocatalyst with carbon dots (DAnTMS/CD). It was reported that this DAnTMS/CD composite could achieve maximum production rates of H_2 and H_2O_2 of 265.0 and 396.7 $\mu mol\ g^{-1}\ h^{-1}$, respectively, with pure water.

14.5 Conclusion

QDs have many advantages compared to traditional materials as photocatalysts. These can create multiple excitons, which could lead to better control over the degree of charge. They can also be more efficient at producing hot

carriers with sufficient energy. Various surface atom ratios of QDs can modify the photoluminescence property. Dangling bonds or defects can reduce long-term photostability and reduce QY. As a result, passivating the surface is critical for enhancing stability and protecting its properties by the shelling of QDs and doping in the QDs.

The role of the quantum dot in photocatalysts developed for photocatalytic and PEC water splitting is a unique function. Water can be converted into hydrogen gas, when solar energy is applied to water in two technologies.

1. Indirectly through concentrated solar thermal and an electrolyzer, as well as solar-converted electricity, and electrolyzer, biological, and thermochemical processes. It has excessive costs, energy loss, and is unfeasible. Besides, the performance of electrolyzers, which have typical commercial efficiencies of around 73%, is always constrained when the energy conversion step is combined with electrolyzers.
2. Direct route including powdered photocatalysts and PEC cells, using photo-/photoelectrocatalysis of water.

The dispersion of powdered photocatalysts into water is ideal for major operations. The system needs to be motivated during the reaction and product separation after the reaction. PEC systems combined solar energy collection and water reduction in one device. Most hydrogen is generated from fossil fuels, including natural gas, oil, and coal. Electron donors like alcohols (methanol, ethanol, and glycerol) are commonly utilized as sacrificial reagents (SEDs) in water to efficiently generate hydrogen by successfully scavenging photogenerated holes to suppress the back reaction.

Quantum Dots

Fundamentals, Synthesis and Applications

With their adaptability and broad applicability, quantum dots have become an increasingly important tool for the development of new materials, approaches, and applications across a wide range of fields. Understanding the molecular fundamentals governing their structures, interactivity, and behaviors can provide a unique insight for researchers and help them design and apply quantum dots in novel ways. *Quantum Dots: Fundamentals, Synthesis and Applications* compiles such key information with practical guidance on quantum dot synthesis and applications.

Beginning with an introduction to quantum dots, Part 1 highlights foundational knowledge such as growth mechanisms, shape and composition, electrochemical properties, and production scale-up for quantum dots. Part 2 goes on to provide practical guides to key chemical, physical, and biological methods for the synthesis of quantum dots. Part 3 reviews a range of important applications of quantum dots, including photocatalysis, energy cells, and medical imaging.

Drawing on the knowledge of its expert authors, this book provides practical guidance for all those who already study, develop, or use quantum dots in their work and is a great introduction for anyone who would like to start doing so.

Key features

- Presents foundational information needed to effectively understand and manipulate quantum dot properties
- Consolidates key methods of quantum dot synthesis in a single volume
- Reviews both current and future practical applications of quantum dots across a range of important fields

About the editors

Dr. Rakshit Ameta has a thoroughly first-class career, securing first position in his MSc. and was awarded a Gold Medal. He was also given the Fateh Singh Award from Maharana Mewar Foundation, Udaipur for his meritorious performance. After completion of his Ph.D., he served in Hindustan Zinc Limited, Vedanta Group for 1 year. Under his supervision, 12 Ph.D. students have been completed their Ph.D. on various aspects of green chemistry. He has around 140 research publications to his credit in journals of national and international repute. Presently, he is the Director, Faculty of Science, J. R. N. Rajasthan Vidyapeeth (Deemed to be University), Udaipur.

Dr. Jayesh P. Bhatt received his MSc. from RSTM Nagpur University in 2011. He did his Ph.D. in the year 2019 from PAHER University, Udaipur and since 2019, he has been working as an Assistant Professor in the Department of Chemistry of the same university. Dr. Jayesh has published 11 research articles in various reputed national and international journals and contributed 12 chapters. Currently, four Ph.D. students are working under his supervision.

Prof. Suresh C. Ameta obtained his master's degree from the University of Udaipur and was awarded a gold medal in 1970. He obtained his Ph.D. degree from Vikram University in 1980. He has served as a Professor and Head of the Department of Chemistry, North Gujarat University, Patan (1994) and M. L. Sukhadia University, Udaipur (2002–05) and the Head of the Department of Polymer Science (2005–08). He has successfully guided 108 students through their course of Ph.D. Dr. Ameta has more than 400 research papers and 36 books to his credit.

FOREWORD

Graphene is an allotrope of carbon, which is in the form of a thin layer with a two-dimensional honeycomb-like structure. It exhibits unique properties such as lightweight, excellent thermal and electrical conductivities, large specific surface area, easy preparation and functionalization, high intrinsic mobility, chemical stability, simple recovery, recyclability, *etc*. Therefore, it has emerged as the most successful entity with a wide range of applications in various medical, chemical and industrial processes, such as flexible electric/photonics circuits, solar cells, drug delivery, tissue engineering, bioimaging, optoelectronics, photodetectors, generation and storage of energy, biosensors, removal of contaminants, catalyst, water and sound proofing, and many more. The editors have made a very judicious choice in selecting graphene and its applications as a topic covering major fields of interest. I appreciate their efforts in compiling the different areas related to graphene and putting them all in a single arena. I believe that this book will get an overwhelming response from the readers.

PREFACE

Catalysis is a fundamental and multidisciplinary phenomenon that has been ruling the energy sector and chemical industry for centuries impacting the world's economy. Not only production processes but even biological and natural reactions are catalytically controlled by enzymes and other substances to maintain life on Earth. Various manufacturing units including petrochemicals, pharmaceuticals, food, polymers, materials, and fine chemicals-based industries along with pollution-abating firms are highly dependent on catalysts. This is because catalysts offer green means for accelerating chemical transformations *via* energy-saving and atom economic pathways.Untill today, multitudes of homogeneous and heterogeneous catalysts have been explored for carrying out several conversions and enhancing the feasibility of reactions. However, the issues of catalyst recoverability and efficiency have been a cause of concern across the globe. More recently, the necessity of environmental conservation has further accentuated the search for sustainable catalysts. In such a scenario, graphene-based catalysts or carbocatalysts have emerged as a boon to meet the growing demand for efficacious, benign and inexpensive heterogeneous catalysts.

Graphene with its distinguished opto-electronic, thermo-mechanical, surface and chemical characteristics is renowned as the most invincible nanomaterial. Ever since the path-breaking discovery of graphene in 2004, the two-dimensional, honeycomb lattice-based material has enthralled the scientific community throughout the world. The exceptional conductivity, tensile strength, stability, large surface area, recoverability, recyclability and ease of functionalization of graphene materials have especially captivated the researchers working in the field of catalysis. Owing to the surge in demand for graphene-based catalysts, graphene research is being carried out at a very rapid pace. Every year new additions to the knowledge and scope of graphene carbocatalysts appear at a considerably large scale. Consequently, this book is an attempt to acquaint readers with the recent advances in the field of graphene carbocatalysis.

The book encapsulates the recent developments involving the syntheses, properties, characterizations, functionalization, and catalytic applications of graphene, its derivatives and composites. The book is in two volumes. The first volume is divided into 10 chapters. In Chapter 1, a brief introduction to carbocatalysis has been laid out. The properties, syntheses and scope of carbocatalysts have been discussed to highlight their significance. Chapter 2 discusses the fundamental structure and properties of graphene and chemically modified graphene contributing to their applications in diverse fields. Chapter 3 describes the diverse synthetic strategies for the preparation of graphene and its derivatives. The advantages of present methods and future challenges related to industrial-scale synthesis have also been outlined in this chapter. Chapter 4 focuses on the latest and most commonly employed characterization techniques used for investigating the morphological, structural, and thermal properties of graphene materials. In Chapter 5, recent trends in functionalization and its role in the catalytic activity of graphene have been put forward. Chapter 6 summarizes the recent progress in the synthesis of graphene-based composites along with their properties and applications in catalytic reactions. The future prospects and challenges towards the design and development of graphene-based nanocomposites for catalytic reactions have also been addressed in the chapter. Chapter 7 reviews the recent advances in graphene-supported palladium catalysts for coupling reactions. It also underscores the synthesis of these catalysts and their mechanistic aspects spanning across a variety of cross-coupling reactions. A comparison of graphene-supported catalysts with traditional catalysts has also been included in this chapter. Chapter 8 provides an in-depth review of recent applications of graphene-based catalysts in multicomponent and domino reactions. In Chapter 9, current progress made

in the field of oxidation and reduction reactions of organic molecules catalyzed by graphene materials has been explored. Chapter 10 accounts for the contemporary trends in the area of graphene-based biocatalysts.

The second volume includes six chapters. Chapter 1 of the second volume incorporates the most recent advances in photocatalytic applications of graphene-based materials such as graphene-based semiconductor photocatalysts for the degradation of various contaminants (treatment of waste water), production of hydrogen, and photocatalytic reduction of carbon dioxide to energy-rich synthetic fuels (combating against global warming and energy crisis), *etc*. Chapter 2 discusses the latest advances in electrocatalysis by graphene materials with a special focus on the electrocatalytic activities of non-metal doped graphene, graphene-2D materials heterostructures, and graphene-plasmonic nanostructures. Chapter 3 provides an overview of the recent advancement made by graphene-based materials including graphene oxide, reduced graphene oxide and graphene oxide quantum dots for hydrogen evolution from light-driven water splitting and future prospects. Chapter 4 highlights the modern trends in the fabrication of graphene-based smart energy materials for applications in various energy storage systems. The future trends and challenges have also been underlined. Chapter 5 underscores the potential utility of graphene materials in electrochemical sensing devices. Chapter 6 concludes the book and reports state-of-the-art graphene carbocatalysis with the future challenges accompanying graphene-based catalysts.

The book covers multidimensional applications of graphene-based materials cutting across various fields ranging from energy generation, chemical synthesis, and electrochemical sensing to photocatalysis. Hopefully, this book will serve as a reference work for all those researchers, students, industry workers and engineers who are interested in graphene research as well as its emerging applications in catalysis and beyond.

At last, we would like to thank all the authors of this book for their invaluable contribution to enriching the content of this book. We are also extremely indebted to the managers, editors, and reviewers of Bentham Science Publications for their magnanimous help throughout the creation and publication of this book. Finally, we are highly grateful to our families for their constant support and inspiration.

CHAPTER 1

Introduction to Carbocatalysis

Pinki Bala Punjabi[1,*] and **Sharoni Gupta**[1]

[1] *Department of Chemistry, University College of Science, Mohanlal Sukhadia University, Udaipur-313001, Rajasthan, India*

Abstract: Carbocatalysis has emerged as a promising field of catalysis. The exceptional surface morphology, pore distribution, thermal conductivity, chemical inertness, electrical property and renewability of carbon materials have rendered them suitable for various catalytic processes namely, photocatalysis, electrocatalysis, biocatalysis and chemical catalysis. Therefore, the introductory chapter on carbocatalysis describes the useful properties of carbonaceous materials which govern their catalytic behaviour. Moreover, synthetic approaches for the fabrication of diverse carbon polymorphs such as active carbon, graphite, fullerene, glassy carbon, carbon black, carbon nanotubes, carbon nanofibres, nanodiamonds, carbon nano-onions, and graphene have also been briefly discussed in this chapter. The scope of carbocatalysts over broad areas has also been elucidated by quoting instances.

Keywords: Carbocatalysis, Electrical Properties, Surface Properties, Sustainability, Synthesis, Thermal Conductivity.

INTRODUCTION

Catalysis is the backbone of chemical transformations which facilitates a sustainable and efficacious means to convert starting raw materials to useful chemical compounds. One of the twelve principles of green chemistry states that the "use of catalysts should be encouraged as these enhance selectivity, reduce the formation of by-products, reaction time and energy requirements" [1]. Therefore, catalytic transformations have become an integral part of environmentally benign chemical processes. Homogenous and heterogeneous catalysts are the two main classes of catalysts that over the past several decades have served as a driving force in achieving high performance conversions by abating the activation energy. Both homogeneous and heterogeneous catalysts have their high points, for instance, homogeneous catalysts have excellent catalytic efficiency owing to

readily accessible active sites [2] while heterogeneous catalysts are quite stable and easy to separate and recover [3]. However, with growing awareness of environmentally friendly protocols, the use of conventional catalysts has become a debatable topic. This is primarily because the traditional catalysis employs acids, bases, transition and non-transition metals which are toxic, expensive, get easily deactivated by impurities and non-reusable.

Sustainability being an essential element of modern chemistry has coerced researchers and chemists globally to look for renewable and cost-effective catalytic systems. The recent emergence of graphene based catalysts has paved way for a green alternative to conventional catalysts. Carbocatalysis *viz.* catalysis driven by carbonaceous materials is not a novel avenue of study. Several carbon based catalyst have been used in the past. Perhaps the beginning of carbocatalysis can be traced back to the year 1854 when Stenhouse observed that activated carbon was capable of oxidizing a mixture of organic gases coming from putrefied biomass [4]. Since then there have been several reports where carbon allotropes were used as catalytic materials. In 1925, Rideal and Wright employed charcoal as a catalyst for the oxidation of oxalic acid [5]. In the 1930s, Kutzelnigg and Kolthoff separately confirmed that activated charcoals were highly suitable for catalyzing the aerobic oxidation of ferrocyanide to ferricyanide [6, 7]. Thereafter in 1979, charcoal was used to catalyze the oxidative dehydrogenation (ODH) reaction of ethylbenzene to styrene [8]. Also, graphite catalyst was employed for the first time by Lucking and co-workers for the oxidative cleavage of 4-chlorophenol, which yielded CO_2, H_2O, and HCl [9]. In another instance, Fortuny *et al.* have also reported oxidation of phenol using active carbon as a catalyst [10]. Despite the good catalytic performance of carbonaceous materials attributable to their versatile porosity and surface properties, carbocatalysis did not achieve the desired level of attention until the discovery of fullerene, carbon nanotubes, and graphene. Further, mostly the carbon polymorphs such as charcoal [11], graphite [12], carbon black [13], and diamond [14] have been used as support in catalytic systems because of their advantages including ease of metal immobilization on carbon, resistance to attack by acids and bases, simple as well as cost-effective preparation, high thermal stability and straightforward recovery of the active phase. Regardless of the beneficial features, some shortcomings such as lack of active sites, microporous structure, hydrophobic character and poor resistance to oxidation stalled the growth of carbon based catalysts in earlier days [15]. However, the recent developments in the synthetic chemistry of carbon have allowed easy modification of the pore size distribution, surface chemistry, and hydrophilicity to afford carbocatalyst with desirable electronic and physicochemical properties, large surface to weight ratio, and better biocompatibility.

The discovery of fullerenes in 1985 was a landmark in the field of carbon science [16]. The unique three dimensional structure of fullerene comprises intricately arranged five and six membered rings of covalently bonded carbon atoms arranged to form spherical shape. The high conductivity (narrow band gap) of fullerene arises from the pi electron delocalization within carbon layers which favours its catalytic behaviour. Functionalization of fullerenes also aids in tuning their electrical properties and serves as a precursor for the preparation of fullerene based nanocatalyst. Ever since their discovery, fullerene based catalysts have been used to catalyze several reactions such as reduction [17], oxidation [18], photodegradation [19], dehydration [20], proton transfer [21], deallylation [22], *etc*.

The birth of nanotechnology proved to be a boon for carbocatalysis. The designing of nanodimensional carbon tubes with readily accessible sites on large surface area revolutionized the field of catalysis. The breakthrough invention of carbon nanotubes in 1991 by Iijima [23] followed by its use as catalyst support in 1994 [24] led to a new generation of catalysts dominated by carbon nanomaterials. Carbon nanotubes belong to the fullerene family and are basically graphite sheets rolled in the form of cylindrical shapes. The excellent electrical conductivity, striking mechanical and thermal stabilities, tolerance against poisoning effect, easily modifiable surface area, and ease of functionalization of carbon nanotubes make them promising catalytic systems [25]. Carbon nanotubes have been widely applied and employed in heterogeneous catalysis [26], photocatalysis [27], and electrocatalysis [28].

One of the lightest and strongest known materials, graphene is a single layered allotrope of carbon that has honeycomb structure and is the most famous carbocatalyst of recent times. The discovery of graphene dates back to 1859 when Brodie while examining the structure of graphite, observed graphene and named it "graphone" [29]. In 2004, the isolation of graphene sheets by Novoselov *et al.* brought about a storm in the field of carbonaceous materials [30]. The extraordinary physicochemical and thermoelectrical properties of graphene such as large specific surface area (theoretically 2630 m^2/g for single-layer graphene) [31], amazing electronic properties and electron transport potential [32, 33], unparalleled flexibility and impermeability [34, 35], sturdy mechanical property [36] and excellent thermal and electrical conductivities [37, 38] attracted enormous interest and resulted in an explosion of research studies in the domain of graphene based materials. In 2009, Lu *et al.* highlighted the use of gold embedded graphene based catalyst for oxidation of CO [39]. Jafri *et al.* also reported nitrogen doped graphene nanoplatelets as a potent catalyst for oxygen reduction reaction [40]. In 2010, Dreyer *et al.* demonstrated graphene oxide as a compatible carbocatalyst for oxidation and hydration reactions [41]. In the same

year, Li and his research group reported electro-oxidation of methanol promoted by Pt nanoparticles on reduced graphene oxide [42]. In another instance, Gao and co-workers used reduced graphene oxide as carbocatalyst for the reduction of nitrobenzene [43]. Since then, a plethora of literature has been available which showcases the abilities of graphene and its derivatives as potent carbocatalysts.

Thus, a bountiful of reusable and economically viable carbonaceous materials are available today which serve as heterogeneous and semi-homogeneous catalysts as well catalytic supports for a range of reactions that find significance in different areas namely, chemical manufacturing, environmental remediation, biomass production, water splitting, energy conversion and storage devices. In the present chapter, an effort has been made to acquaint the readers with the properties, syntheses and scope of carbocatalysts (Fig. **1**).

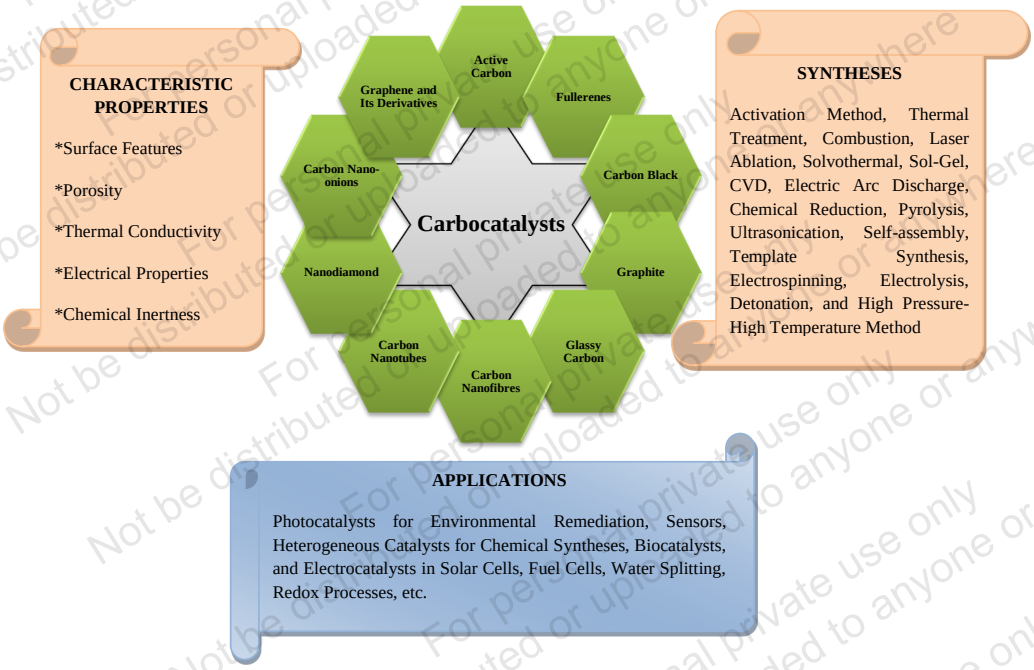

Fig. (1). Properties, syntheses and scope of carbocatalysts.

PROPERTIES OF CARBOCATALYSTS

Now let us delve into the properties of carbon materials that render them suitable as catalytic systems.

Not be distributed or uploaded to anyone or anywhere
For personal private use only

Surface Properties

It is well known that for any catalyst, surface features are crucial in governing its catalytic activity. The surface properties of carbon materials depend on the spatial arrangement of carbon atoms which in turn are based on the method of preparation or treatment used to synthesize these materials. The presence of a high density of pores and large surface area on carbonaceous materials play a key role in the adsorption of reactant molecules [44]. The introduction of defects in carbon atom layers present in carbon based materials and eases of their functionalization make their surface apt for catalysis. These structural defects particularly on the edges serve as active sites for binding of reaction molecules being easily accessible.

The defects in carbon materials can be introduced by thermal treatment or doping. For instance, Qiu *et al.* have reported that the amount of surface defects is directly related to the catalytic efficiency of activated carbons [45]. They used a simple thermal treatment method aided by a nitrate solid-phase oxidative method to increase the amount of surface defects on the activated carbons and observed their catalytic effect on the hydrochlorination of acetylene. It was reported that this treatment removed oxygen moieties and introduced defects on the edges of active carbons. Armchair and zigzag edges were observed in active carbon due to the stacking arrangement of nanosized graphitic layers, thereby populating the edges with active sites. In another study, it was reported that selective doping of carbon materials with heteroatoms induces catalytically beneficial defects. Chen *et al.* doped carbon nanosheets with B-N pairs and employed them as a catalyst to promote ammonia synthesis [46]. It was highlighted that the B-N doped carbon nanosheets showed superior activity compared to metallic catalysts for the nitrogen reduction reaction. The better electrocatalytic behavior of B-N doped carbon nanosheets was attributed to the fact that doping resulted in generating sufficient active sites at the edge carbon atoms.

The functionalization of carbon surfaces causes changes in the surface energy as well as chemical reactivity of the materials. Surface functional groups may increase free valences on the edges of the external surface, thereby increasing the catalytic activity [47]. The functional groups also assist in tuning the hydrophilicity of carbon materials and are capable of altering the acidic and basic character of these materials [48, 49]. Oxygen, nitrogen, hydrogen, sulphur, phosphorous and halogens functionalities are commonly used for this purpose. Chen *et al.* functionalized carbon nanotubes with oxygen functional groups [50]. Several oxidants like H_2O_2, $KMnO_4$, HNO_3/H_2SO_4 were used to functionalize the nanotubes. After functionalization, the pH_{pzc} (pH at which net surface charge on carbon is zero) was measured by the chemical titration method [51]. It was

reported that after functionalization the carbon surface became acidic due to the presence of functional groups like carboxyls which decreased the pH_{pzc} value making the surface more hydrophilic [52 - 54]. It was also reported that the presence of carboxylic functional groups also enhanced the dispersion of Pd and Pt metals on CNTs *via* the formation of chemical bonds, which hindered the agglomeration metal particles on CNTs and minimized the sintering propensity of the formed Pd–Pt particles across the CNT surface in the calcination and reduction process [55, 56]. This increased uniform dispersion of Pd-Pt on functionalized CNTs resulted in improved catalytic efficiency for hydrogenation of naphthalene to tetralin. In another study, it was reported that the functionalization of sulphonic acid group on graphene oxide improved its hydrophilicity as well as permeability [57].

It has been also reported that surface functionalization also improves the adsorption property of carbon materials. Sun *et al.* functionalized carbon beads *via* surface amination treatment and used it to study CO_2 capture [58]. It was demonstrated that the surface modifications enhanced the adsorption of CO_2 without compromising the desirable spherical morphology and mechanical strength of the activated carbon beads. This was attributed to surface modification of carbon, greater number of N-H functionalities resulted in stronger binding between CO_2 and C-N-H groups than that of C=N-C.

A study conducted by Arrigo *et al.* showed that the functionalization of nanocarbons aids in the regulation of their acidic/basic character [49]. They treated oxidized carbon nanofibres with ammonia and evaluated the surface acid-base properties. It was reported that the samples contained both O and N species on the surface which served as acidic and basic sites. It was further illustrated that the population of O and N functionalities depended on temperature and could be controlled to modify the acid-base properties of the carbon surface. At 473 K, nitrogen moieties were incorporated on the surface as a consequence of the reaction of carboxylic acid sites with ammonia, thereby generating a bifunctional hydrophilic material with both acidic and basic sites on the carbon surface. Further raising the temperature to 873 K resulted in strong basic sites leading to a hydrophobic carbon surface. Thus, it was proved that altering the surface functionalization once can modify the acid-base nature of the carbon surface.

The specific surface area of materials is one the most imperative factors that directly affect catalysis. Greater surface area means better ease of access to active sites. The size reduction of particles causes the enhancement in the surface area of a substance. The surfacing of nanotechnology has resulted in the development of methods through which one can get nanodimensional materials with extremely large surface area. The nanocarbon materials with higher surface to volume ratio

have therefore emerged as very effective carbocatalysts. For example, Pan *et al.* prepared porous N-doped carbon nanotubes (NCNTs) by pyrolysis of polypyrrole nanotubes and KOH activation at different temperatures 800 °C, 900 °C and 1000 °C [59]. The prepared nanotubes were used as electrocatalysts for the oxygen reduction reaction. A BET analysis was conducted to deduce the surface area of the nanotubes. It was reported that the specific surface area of polypyrrole nanotubes, NCNT-800, NCNT-900, and NCNT-1000 was 26, 1057, 1402, and 1137 m^2/g, respectively. The assessment of ORR in a standard three electrodes cell showed that the NCNT-900 and NCNT-1000 were the most efficient catalysts in promoting the reactions. Furthermore, the nanotubes exhibited superior catalytic activities as compared to the commercially available Pt/C catalyst. It was thus highlighted that the high surface areas in porous nanotubes afforded active sites for diffusing O_2 and KOH electrolyte thereby enhancing the rate of ORR.

Pore Size Distribution

The porosity of carbon materials is another important factor that influences their catalytic performance. Porous carbon materials can be classified as microporous (<2 nm), mesoporous (2-50 nm), and macroporous (>50 nm) on the basis of their pore diameters [60]. The pore volume and pore-size distribution play a crucial role in shape-selective catalysis [61]. Porosity in a material enhances catalytic activity not only by increasing accessibility to active sites albeit also by facilitating the mass transfer. Thus, by tuning the porosity one can induce desired catalytic properties in a material. Ferrero *et al.* investigated nitrogen-doped carbon microspheres with tunable porosity as electrocatalysts for the oxygen reduction reaction (ORR) [62]. It was reported that the catalyst was prepared by nanocasting using pyrrole as N-containing carbon precursor and porous silica microspheres as a template. Using two different silica samples as templates, the porosity of the microspheres was tuned from a micro- to a mesoporous network. The prepared catalytic system was applied to ORR and it was found that mesoporous electrocatalyst was more efficient than microporous one. This result was attributed to better accessibility of the active sites in the case of the mesoporous microspheres compared to the microporous ones. This is because in microporous materials the diffusion of reactant molecules becomes restricted due to small pore size and volume. It was further deciphered that the improved accessibility to the active sites on the surface of the mesoporous microspheres led to increase in mass-transfer reactions during the electrochemical process, thereby increasing the rate of catalytic reduction. Consequently, it can be said that pore size and volume are significant contributing factors in carbon based catalysis.

Thermal Conductivity

Thermal conductivity is another important criterion in carbocatalysis. Thermal conductivity is the ability of an object to conduct heat. Heat transfer is an important phenomenon in catalysis, particularly for strongly endo- and exothermic reactions in which fast heat management is advantageous for active sites [63]. Heat conduction in materials usually occurs due to the transmission of lattice vibrations known as phonons [64]. Carbonaceous materials like graphite, diamond, graphene, carbon fibres, and carbon nanotubes are well known for their thermal properties. The arrangement and coordination of carbon atoms along with defects in these materials are the main reasons for high thermal conductivities [65, 66]. A thermally conductive cobalt loaded graphite based catalyst for low temperature based highly exothermic Fischer-Tropsch synthesis (FTS) was reported [67]. It was reported that the use of this catalyst resulted in high productivity of hydrocarbons. This is because the incorporation of exfoliated graphite in the catalyst provides an amalgamation of extensive surface with high thermal conductivity and durability for the gasification process. Thermal analyses of graphite and aluminium based catalysts showed that the thermal conductivity of graphite is twice more than aluminum based catalyst and 30 times greater than a cobalt catalyst without heat conducting agents. It was further revealed that due to the high thermal stability of graphite, the catalyst survives overheating while the aluminum based counterpart is limited to 450 °C or even lower temperature because of irreversible effects such as metal pre-melting and oxidation. Hence, it is clear that thermally conductive as well as stable catalysts are perquisite for promoting reactions that require conduction of heat energy or heat removal.

Electrical Properties

To understand the electrical properties of carbonaceous materials, first, it is imperative to clarify the concepts of electrical resistivity and conductivity. Electric resistivity is a fundamental property of a material due to which it opposes the flow of electric current [68]. Mathematically, electric resistivity (ρ, Ωm) is defined as the ratio of electrical field (E, Vm^{-1}) inside the material to the electric current density (J, Am^{-1}), eq. (1). In other words, the resistivity is the resistance (R) offered by a material with unit cross sectional area (A) and unit length (l), eq. (2),

$$\rho = \frac{E}{J} \quad \textbf{(1)}$$

$$\rho = R.\frac{A}{l} \quad \textbf{(2)}$$

Not be distributed or uploaded to anyone or anywhere
For personal private use only

Electric conductivity (σ, $\Omega^{-1}m^{-1}$ or Sm^{-1}) is the property of a material by the virtue of which it conducts electricity. It is the reciprocal of electric resistivity. Consequently, both the terms resistivity and conductivity are interrelated and form the basis of the classification of materials [68]. On the basis of electric conductivity or resistivity, materials can be classified as conductors (materials that conduct electric current), insulators (materials that resist electric current) and semi-conductors (materials that intermediate between conductors and insulators).

The electrical properties of carbon materials are very much dependent on the structural attributes and type of treatment given to them. Different allotropes of carbon show different degrees of conductivities due to structural differences [69]. For instance, diamond exhibits low conductivity because each carbon atom is sp^3 hybridized and bonded to four carbon atoms by strong covalent bonds. Therefore, no electrons are available for conduction. It has a wide band gap of 5.5 eV [70]. While in graphite the sp^2 hybridized carbon atoms are arranged as two-dimensional hexagonal lattice structure with carbon sheets stacked one above another and each carbon has one free electron. The sheets are held by weak van der Waals forces, electrons freely move throughout the layered structure. Graphite, thus, has a small band gap (40 meV) between valence and conduction bands and behaves as a conductor similar to metal [71].

Fullerene, a carbon polymorph, is a large caged polyhedral molecule with either fcc or bcc packing of atoms. In fullerene sp^2 carbons are directly bonded to three neighbors in an arrangement of five- and six-membered rings. Fullerenes are basically semiconductors, however, by doping heteroatoms, superconductivity can be induced [72].

Carbon nanotubes (CNTs) are rolled-up graphene sheets with cylindrical structure. These are of two kinds, single-walled carbon nanotubes (SWCNT) with a diameter in the nanometer range and multi-walled carbon nanotubes (MWCNT) are nested single-walled carbon nanotubes held together by van der Waals forces with a diameter of less than 100 nm. The interlayer distance in multi-walled carbon nanotubes is 0.34-0.39 nm [73]. SWCNTs can have an armchair, chiral, and zigzag geometries depending on the wrapping of cylinders while MWCNTs are of two types Russian Doll model and the Parchment model [74]. When the diameter of the outer nanotube is greater than the inner nanotube then, it is called the Russian Doll model. Whereas, when a single graphene sheet wraps around itself multiple times just like a scroll of paper, it is called the Parchment model. On the basis of structural symmetry, carbon nanotubes can exhibit conducting or semiconducting nature [75].

Graphene is a two dimensional single sheet of carbon atoms arranged like a honeycomb lattice and displays unusual electrical properties. In graphene, each C atom is linked to three other carbon atoms, leaving an electron freely available for electronic conduction. These mobile electrons are called pi (π) electrons and are located above and below the graphene sheet. Graphene is a zero-gap semiconductor because its conduction and valence bands meet at the Dirac points, where the effective mass of electrons (or holes) is zero. The free electrons in graphene interact with the periodic potential of the honeycomb lattice, generating new quasiparticles that have lost their mass or rest mass and hence, called massless Dirac fermions. Thus, graphene conducts electrons with high velocity and the lattice symmetry inhibits direct backscattering of electrons, enhancing the electrical mobility and conductivity [76].

The remarkable electric conductivities of graphite, fullerenes, nanotubes, and graphene make them highly suitable as a catalyst for various redox reactions. The electrical properties of carbon materials arising from their unique structures can further be tuned by functionalization, heteroatom doping and controlling the temperature of graphitization or carbonization [77].

Functionalization of carbon surface alters the electrical behaviour of carbon material by modifying their structure. In one such instance, Suslova *et al.* have reported that the electrical conductivity of nitrogen doped carbon nanotubes increased considerably with an increase in oxygen functionalities on their surfaces owing to elevation in the density of defects in their structural arrangement [78]. In another example, it was shown that graphitized carbon nanofibre bearing oxygen functional groups demonstrated high electrocatalytic activity as bifunctional electrode for vanadium redox flow battery [79]. The high catalytic performance of carbon nanofibres was attributed to an increase in ion diffusion and electron transfer processes owing to improved electrical conductivity and surface area due to presence of surface functionalities.

Doping is a method by which introduction of heteroatom results in generation of holes or addition of an extra electron in a substance. This process leads to decrease in band gap of valence and conduction bands, thereby, improving the conductivity of semiconductors. Heteroatom doping is therefore a strong tool for tuning the electrical conductivities of carbon materials. Han *et al.* studied the effect of N-doping in carbon nano-onions [80]. The N-doped carbon nano-onions (N-CNOs) were prepared by a one-step, *in situ* flame synthesis technique using clarified butter and acetonitrile as precursors. The prepared N-CNO was than employed as catalyst for ORR process in a microbial fuel cell. It was reported that the catalytic activity of N-CNO was 5.4 times higher than CNO. This high performance was ascribed to the presence of nitrogen atoms in carbon framework.

Through electrochemical impedance spectroscopy, it was elucidated that the conductivity of N-CNO is higher than CNO due to N-doping. It has been explained that the sp^2–C atoms adjacent to N atoms and N atoms stimulate the electrostatic adsorption of oxygen molecules leading to sharp reduction in the kinetic barrier for the ORR process [81]. Simultaneously, N-doping causes electron excess in the delocalized π-system which results in enhancement of electrical conductivity. Finally, the high electrical conductivity induces electron transfer during catalysis, assisting the contribution of C-N active sites and improving the ORR activity on the whole [82]. As a result, the high ORR catalytic performance of N-CNO can be attributed to the high electrical conductivity arising from N-doping.

It has also been reported that thermal [83] and graphitization treatments [84] generally result in metallic conductivity in carbon materials while oxidation induces semi-conductivity due to π-electron delocalization [85]. Therefore, by applying different treatments one can tune the electrical properties of carbocatalysts.

SYNTHETIC STRATEGIES FOR CARBOCATALYSTS

As is well known that synthetic methods greatly influence the properties of a material, therefore, in this section some strategies employed for synthesis of carbocatalyst have been discussed. So many methods for synthesis of carbon materials are reported that a whole chapter can be devoted to the synthetic aspects of carbon allotropes. However, since the book deals with graphene here we have highlighted some important methods only.

Active Carbon

Activated carbon is highly porous form of carbon. Coal, wood, agricultural wastes or biomass, ionic liquids, salt solutions, *etc*. are used as precursors to prepared activated carbon or charcoal [86]. Physical and chemical activation methods are commonly used to prepare active carbon materials. Before activation, carbonization and de-ashing is performed as pre-treatment. In carbonization the raw materials are subjected to heat treatment or pyrolysis at high temperatures around 573.15 K to 1173.15 K in order to eliminate non-carbon materials and volatile impurities. This result in formation of char after rearrangement of carbon atoms into graphitic sheets stacked above one another to form rigid microcrystals with voids which constitute the pore structure [44]. Ahead of activation, ash and mineral content of the carbon materials is reduced by de-ashing or demineralization technique *via* chemical leaching. In this process, acid and alkali solutions are used to demineralize the carbon raw materials [87]. For instance,

Ahmad *et al*. performed acid treatment of cocoa shell pellets with 1M HCl which reduced the ash content to less than 10% [88]. In another study, it was reported that high ash content reduced the adsorption property of activated charcoal prepared from stone coal ore hence, to improve the adsorption. The stone coal ore was pre-treated with HF and H_2SO_4. The acid treatment reduced the contents of mineral atoms like Fe, Mg, Ca, Si, *etc*. resulting in stone coal ore with 74.76% carbon content [89]. Similarly, KOH promoted de-ashing of rice husk was reported by Shen and Fu which resulted in highly porous biochar [90].

Next step involved in formation of activated carbon is activation. Activation can be carried out in two methods: physical and chemical. Physical activation includes use of carbon dioxide, air, steam or other gaseous agents at 1073.15 to 1273.15 K to remove oxides of carbon from char and improving the porosity of carbonaceous materials. Zhou and co-workers have reported preparation of highly porous activated carbon from waste tea *via* physical activation with steam [91]. It was further highlighted that typically micropores were developed when the activation temperature was below 800 °C while activation above 800 °C enriched the carbon with both micropores and mesopores.

Chemical activation involves single-step carbonization and activation of carbon materials by impregnating them with chemical agents such as KOH, $ZnCl_2$, H_3PO_4, $FeCl_3$, $CaCl_2$, H_2SO_4, NaOH, $MgCl_2$, K_2CO_3, HNO_3, *etc*., followed by thermal treatment [86]. The chemical agents due to dehydrating property result in generation of a rigid framework which is less prone to reduction in volume during carbonization, thereby generating excellent yields of activated carbon [92, 93]. Moreover, since chemical activation is performed at lower temperature than physical activation, it offers better control of porous structure [94]. However, from environment point of view physical activation is better as it avoids use of chemical agents while chemically activated materials contain some amount of inorganic matter [95]. Recently, Chen *et al.* have demonstrated synthesis of activated carbon with large surface area from tobacco stem [96]. Chemical activation was performed using KOH, K_2CO_3 and $ZnCl_2$ as activating agents. It was reported that $ZnCl_2$ caused higher activation of tobacco stem compared to KOH and K_2CO_3. Further, increasing the concentration of $ZnCl_2$ enhanced the development of new pores and the widening of existing pores. Furthermore, activation of carbon with K_2CO_3 resulted in high oxygen functionalities on the surface. Thus, it is evident that nature of chemical agent and concentration affects the activation process as well as surface properties.

Graphite

Synthetically, graphite is prepared *via* thermal treatment of petroleum coke or coal-tar. Hydrothermal methods involving treatment of polymers and metal carbides can also be used to produce graphitic materials. Of late, graphite encapsulated nanoparticles have also emerged as potent carbocatalysts. These can be fabricated by several methods such as pyrolysis, template synthesis, chemical vapor deposition, arc discharge, laser ablation technique, *etc*. Li *et al.* have demonstrated hydrothermal synthesis of graphite encapsulated molybdenum carbides [97]. The graphite encased molybdenum carbide nanoparticles were prepared by the hydrothermal carbonization of a mixture of glucose solution and ammonium molybdate followed by temperature programmed reduction under mild conditions. The prepared graphite encapsulated nanoparticles showed high catalytic efficiency for conversion of guaiacol to phenolic compounds in methanolic medium. In another study, graphite encapsulated gold nanoparticles displaying excellent electrocatalytic activities towards oxidation reduction reaction were prepared by laser ablation method. The process of laser ablation involved installation of Au target in a vessel containing graphite precursor-acetone (16 mL). Thereafter, the revolving Au target was ablated by a focused beam of laser with wavelength of 1064 nm, 10 Hz pulse repetition rate and 100 mJ pulse energy for 30 min. Finally, the graphite encased Au nanoparticles were obtained by centrifugation followed by freeze drying. Thus, laser ablation technique afforded a facile and efficient route to synthesis of graphite encased nanoparticles.

Recently, expanded graphite has been employed as catalyst for oxidation reaction [98]. Expanded graphite is a type of graphite with interlayer spaces. The expanded graphite is prepared by oxidation of natural graphite flakes using acids like nitric acid and sulfuric acid and oxidants like potassium permanganate, chromic acid, hydrogen peroxide, *etc*. Then, the mixture is subjected to high temperature which causes expansion and swelling of graphite resulting in separation of layers leading to formation of its expanded form.

In recent past, hydroxylated high surface area graphite has also been used as carbocatalyst for ozonation. Usually, oxygen functionalized graphite are prepared *via* oxidation using strong acids and mechanical or thermal exfoliation methods. In a method reported by Bernat-Quesada *et al.*, the water soluble graphite was synthesized by oxidation of graphite by nitric acid [99]. Dispersion of graphite in nitric acid followed by heating at 83 °C for 20 h followed by filtration and drying resulted in formation of oxygen functionalized graphite on edges as well as basal planes [48]. In another method, the workers used ball milling technique to fabricate hydroxylated graphite. In this method, graphite, KOH and water were

loaded in a grinding jar of planetary ball mill. The jar was agitated at 300 rpm for 10 hours at ambient temperature. Later, the mixture was filtered and dried to obtain graphite functionalized with oxygen moieties on the edges.

Xu *et al.* have also reported the synthesis of functionalized graphite felts as catalyst for oxidation of hydrogen sulphide [100]. The commercial graphite felts bearing oxygen functionalities were prepared by treatment with nitric acid. According to the method, graphite felts were first heated at 500 °C for 1 hour in air. Then, the felts were loaded in a tubular reactor and heated at 250 °C using an external electric furnace [101]. The reactor loaded with the felts was connected to a round bottom flask (RBF) containing 65% HNO_3 solution (150 mL). The temperature of the RBF was maintained at 125 °C and the solution was continuously stirred magnetically. The gaseous acid passed through the felts for several hours causing their oxidation. The sample was then washed using deionized water and dried at 130 °C overnight. The acid treated functionalized graphite felts exhibited large surface area and it was concluded that the structural defects in graphite felts as well as oxygen groups on them served as active sites for oxidation of hydrogen sulphide.

Fullerenes

Fullerenes and their composites are widely used as catalysts. Fullerenes are giant caged carbon allotropes that are generally prepared by arc discharge and laser ablation of graphite, and combustion of hydrocarbons. In a typical arc discharge method, electric current is struck between graphite or carbon anode and cathode electrode in an inert atmosphere. The electric discharge produces soot which is collected and fullerene is then extracted from the soot by solvent extraction method, sublimation or supercritical fluid extraction technique. Generally for fullerene synthesis, an alternating current between the graphite electrodes in He atmosphere of about 200 Torr is used to produce soot containing C_{60} and C_{70} molecules [102].

The laser ablation technique makes use of a pulsed laser beam which is focused on the surface of carbon sample at high temperature (usually 1000 °C). Thus, the ablation of carbon results in fragments which form fullerenes [103]. Also, hydrocarbon combustion in presence of electric field acting on the flame is widely used to achieve soot-containing fullerene [104].

Additionally, several fullerene based complexes are also well known as catalysts and can be prepared by different methods. For instance, Sabounchei and co-workers have prepared mono- and bidentate palladium(0)- [60]fullerene based complexes as catalyst for Mizoroki-Heck coupling reaction [105]. The synthetic strategy involved a Schlenk tube containing C_{60} (0.05 mmol, 0.036 g) and

$Pd(dba)_2$ (0.05 mmol, 0.029 g) in 15 mL of toluene. The reaction mixture was stirred for 15 min at room temperature during which the color changed from purple to black. Thereafter, a phosphorus ylide solution (0.05 mmol) in toluene (5 mL) was injected into the reaction solution *via* a syringe pump. Further, a 2 hour stirring was continued at ambient temperature which resulted in deep green solution. Dark green crystals were obtained by treating the solution with n-hexane overnight and later washing with diethyl ether.

Further, several fullerene based composites fabricated by sol-gel method, chemical reduction, ultrasonication, hydro- or solvothermal technique, *etc*. serve as useful catalysts [106]. For example, Liu *et al.* have reported synthesis of silver (I) doped fullerene by liquid- liquid interfacial precipitation method [107]. The method involved mixing of saturated solution of fullerene (approx. 2.8 mg/mL) in toluene with isopropyl alcohol saturated with silver nitrate at ambient temperature. The bilayer so formed was kept still under room conditions for 3 hours. Thereafter, centrifugation of the mixture at 7000 rpm for 5 minutes resulted in precipitation of crystalline solid which was dried under nitrogen stream. Then, chemical reduction the $AgNO_3$ complex encapsulated fullerene crystals with hydrazine hydrate solution (1.3% wt.) resulted in formation of Ag(I)-fullerene composite. Finally, the composite was washed with deionized water and ethanol to remove excess silver ions. The prepared Ag(I)-fullerene composite was used as a catalytic system for reduction of 4-nitrophenol and photo-degradation of orange G dye.

A self assembled method based on hydrothermal mode for synthesis of amine functionalized fullerene decorated with palladium nanoflowers was reported by Li and Han [108]. Initially, amine functionalized fullerene was prepared by dissolving ethylenediamine in ethanol-water system (5:1). Then this solution was added drop by drop to toluene saturated with C_{60} fullerene and sodium hydroxide with continuous stirring. The stirring was continued for 5 days in argon atmosphere at room temperature, later the solution was filtered, centrifuged, and washed with ethanol and distilled water for a number of times. Eventually, dark brown solid products were obtained after drying in vacuum for 24 hours at 60 °C. For preparation of composite of fullerene, palladium chloride was dissolved in HCl and DMF and mixed with functionalized fullerene. The reaction mixture was then placed in autoclave for 6 hours at 140 °C in nitrogen atmosphere. The obtained product was washed with ethanol and vacuum dried overnight to yield amine functionalized fullerene decorated with palladium nanoflowers which displayed excellent electrocatalytic effect for reduction of *p*-nitrophenol.

Glassy Carbon

It is a type of carbon material which combines characteristics of both glass and ceramic materials with that of graphite. It is a commonly used electrocatalyst or electrode material. The strategy for fabrication of glassy carbon is based on pyrolysis of polymeric materials at elevated temperatures of about 3000 °C [44, 109]. The mechanism basically involves breakdown of carbon-heteroatom bonds in polymers and generation of C-C bonds [110 - 112]. Initially, hydrocarbon radicals are generated with their highest concentration at around 600 °C [113] and after 800 °C or higher temperature, a network of graphene fragments develop [114]. Further, annealing process results in formation of cross-linked carbon network and removal of volatile by-products like oxides of carbon, water, methane and small hydrocarbons [115]. For instance, Jurkiewicz *et al.* prepared glassy carbon by carrying out pyrolysis of polymeric furfuryl alcohol under Ar gas flow at varied temperatures ranging from 600 to 2500 °C at different heating rates [116]. The carbonized samples were then cooled in argon atmosphere resulting in glassy carbon with fullerene-like or nanotube-like elements in its structure. It was also reported that pyrolysis up to 1000 °C resulted in increase in fullerene-like non-planar sp^2 carbon bonds. But on further increase in pyrolysis temperature the amount of non-planar sp^2 bond content decreased.

Recently, a nitrogen enriched glassy carbon was prepared as an electrocatalyst for hydrogen evolution reaction by Thirukumaran and his research group [117]. Initially polybenzoxazine was synthesized by step-wise polymerization of benzoxazine. The carbonization of polybenzoxazine at 600 °C for 5 hours under nitrogen atmosphere was performed. The resultant carbonaceous material was then activated by adding KOH solution followed by water elimination through evaporation at 120 °C. Subsequently, the carbon material was heated in a tubular furnace for an hour at 600 °C to obtain nitrogen enriched glassy carbon. This method thus offered an efficient method for synthesis of glassy carbon electrocatalyst.

Carbon Black

Carbon black is composed of colloidal carbon particles and is usually synthesized *via* partial combustion or thermal decomposition of petroleum products. Carbon blacks are extensively used as electrocatalysts for redox processes. Diverse thermal methods for carbon black synthesis are summarized below [118].

Channel Black Process

In this process, combustion of natural gases using a continuous small wide luminous fan-shaped flame occurs. This process yields carbon black with a particle size of approximately 10-30 nm.

Gas Black Process

It involves thermal oxidative decomposition, where the formation of carbon black takes place in diffusion flame.

Thermal Black Process

In the thermal black process, thermal combustion of natural gas into elemental carbon and hydrogen takes place at high temperatures to produce carbon black and tail gas. The sizes of obtained carbon black particles are about 180 nm.

Acetylene Black Process

The method involves constant thermal decomposition of acetylene gas in the absence of oxygen gas to generate carbon black as aerosols.

Lamp Black Process

It includes partial combustion of carbon materials such as resins, fatty oils and acids, coal tar, *etc*., resulting in the deposition of carbon in the form of soot. Carbon black particles so obtained range in the size from 110 to 120 nm.

Furnace Black Process

In this process, aromatic oils are pyrolized by exposing them to a hot gas stream to produce carbon blacks with particle sizes of about 20-100 nm.

Besides these methods, carbon black is also obtained by plasma synthesis. An arc discharge plasma method coupled with thermal pyrolysis for the synthesis of carbon black was demonstrated by Sun *et al.* [119]. An apparatus composed of a plasma generator, thermal pyrolysis device, gas injector, power supply and collecting device was used for this purpose. Thermal plasma was generated by electrodes supplied with 10 kV power. Argon was injected into the device for 5 min. to firstly drain out oxygen and then mixed with propane at definite rate of volume. As the propane gas flowed into the plasma region, carbon black was produced instantly. Then the thermal pyrolysis furnace pyrolyzed the un-reacted propane. Finally, carbon black was collected from the bottom of sand core funnel connected with a vacuum pump.

Functionalized carbon black has also gained attention as catalyst. Recently, oxidized carbon black has been employed as a catalyst for the synthesis of benzodiazepines [119]. The oxygen functionalized carbon black was prepared by Hummer's method. In this method, sulphuric acid (120 mL) and sodium nitrate (2.5 g) were mixed with 5g of carbon black in a round bottom flask kept on an ice bath. The suspension was magnetically stirred and then 15 g potassium permanganate was added gradually. The mixture was subjected to heating at 35 °C and stirred for about 24 hours. Then, 700 mL deionized water was added in small portions resulting in black slurry for carbon black under stirring. Finally, 5 mL of hydrogen peroxide solution (30 wt%) was added to the slurry. The obtained sample was poured into deionized water and then centrifuged for 15 min at 10000 rpm. The sample was then washed with deionized water and HCl (5 wt %) and later dried to obtain oxidized carbon black. The optimal conditions for highly graphitized carbon black production were a discharge current of 0.8 A, 120 L/h of argon flow rate, 80 ml/min of propane flow rate and pyrolysis temperature at 700 °C.

Also, carbon black based composites to have found applications as electrocatalysts. In a work conducted by Lim *et al*., TiO_2/carbon black composite was prepared and used as a catalytic electrode in dye-sensitized solar cells [120]. The composite formation involved pulverization of carbon black followed by its calcination in a muffle furnace at 500°C for 2 hours by placing the carbon black in 80-unit mesh. The calcinated carbon black was again ground and thermally treated at 300 °C for 2 hours to obtain carbon black powder with a particle size of about 80 nm. Then, nano-TiO_2 was prepared by the modified Burnside method. Finally, TiO_2/carbon black composite was fabricated by mixing carbon black powder with TiO_2 NPs followed by ultrasonication for 10 min. at 750 W. Then, the addition of 100 µl of Triton X-100 to the mixture followed ultrasonic treatment for 10 min. yielded the TiO_2/carbon black composite. The prepared composite was subsequently used as the counter electrode material in solar cells.

Carbon Nanomaterials

Carbon Nanofibres

Carbon fibres are carbon containing fibres of diameter of the order of few micrometers that find applications in industries due to their enormous tensile strength and thermo-chemical conductivity and stability. In last few years nanodimensional carbon fibres have attracted huge attention in the field of catalysis due to their advanced chemical and electrical activities along with large surface area. Carbon nanofibres are usually prepared by chemical vapour deposition method (CVD), catalytically promoted CVD (CCVD), electrospinning

and template synthesis techniques. CVD is a well acknowledged method for synthesis of 2-dimensional nanomaterials. The method is based on decomposition of vapour or gaseous precursors on a substrate for preparation of materials at elevated temperature in presence of vacuum. The CVD method was explored by Hulicova-Jurcakova *et al.* for synthesis of carbon nanofibre [121]. Carbon precursors like methane and acetylene were used for this process and nickel supported on γ-alumina was used as substrate. The reaction was carried out in tubular furnace with a heating rate of 10 °C/min at 500°C and 700°C, respectively. The obtained carbon samples were purified in reflux system using 5 M nitric acid solution for 6 h, the obtained solution was filtered and dried to obtain carbon nanofibres. Highly graphitic carbon nanofibres were obtained by this CVD method.

Another important method that has emerged for nanofibre synthesis is CCVD, in which catalyst based chemical vapour decomposition, is carried out. Miniach and co-workers have reported a CCVD method for synthesis of carbon nanofibres [122]. They used hydroxyapatite-supported nickel catalyst (Ni/HAp) on which methane decomposition occurred resulting in the formation of herringbone bamboo-like carbon nanofibres. In this method, first Ni/Hap was loaded in a quartz tube placed inside a horizontal furnace. First the catalyst was reduced under H_2 flow (150 ml min^{-1}) at 450-650°C for 10-120 min. Afterwards, the methane and hydrogen gases were made to flow through the tubes at 650°C for 3-180 min. Later the nanofibres were cooled down to room temperature in N_2 atmosphere and then treated with 5% HCl in a sonication bath for 2 hours to remove the excess catalyst. Finally, the carbon nanofibres were washed with deionized water and dried.

Electrospinning is a commonly used method for the fabrication of nanofibres from polymeric materials using high power electric force. Recently, Alarifi *et al.* prepared carbon nanofibres from polyacrylonitrile (PAN) by electrospinning technique [123]. It was reported that a homogeneous solution of PAN was prepared by dissolving PAN in DMF and stirring it at 500 rpm for an hour. The solution was then transferred into a 10 mL syringe and using electrospinning technique with the electric field of 25kVat injection rate of 1 ml/h and a spinneret-to-collector distance of 25 cm, the nanofibres were formed. Thereafter, thermal treatment of nanofibres in oxygen atmosphere at 270°C for an hour followed by carbonization in argon atmosphere at different temperatures 750, 850, and 950°C was carried out resulting in high carbon content nanofibres.

Template synthesis is also one widely used method for synthesis of nanofibres. The strategy involves use of a nanoporous membrane as a template for synthesis of nanofibers from diverse materials such as carbon, polymers, semiconductors,

and metals [124 - 126] (Huczko, 2000; Hulteen and Martin, 1997; Toro and Buriak, 2014). A template based synthesis for carbon nanofibres were reported by Li *et al.* [127]. The method involved addition of anhydrous zinc acetate to ethylene glycol followed by stirring of the mixture at 150 ° C for 90 min. Then, the mixture was subjected to centrifugation and the obtained slurry was calcinated at 600 ° C for 2 hours in argon atmosphere. Later, the composite was immersed in a 2.0 M HCl solution with overnight stirring to obtain the nanofibres. The carbon nanofibres were then purified by washing with water and ethanol and then dried. Mesoporous carbon nanofibers were obtained after being washed with water and ethanol, and then dried at room temperature. The carbon nanofibres produced by this method were highly mesoporous and were used as electrodes.

Carbon Nanotubes

There are several methods for fabrication of carbon nanotubes (CNTs) namely, CVD, arc discharge, laser ablation, electrolysis, ultrasonication techniques, *etc*. Verma *et al.* have demonstrated CNT fabrication using CVD approach [128]. An automated CVD reactor was used and iron catalyst supported over magnesium oxide was loaded on quartz boats of the reactor. Argon and hydrogen gases were flown into the reactor at a rate of 100 ml/min. at 25 °C for 5 min. Then, temperature was raised to 750 °C and after 10 minutes acetylene along with hydrogen was flown in the reactor for 15 min. at the rate of 300 ml/min. and 100 ml/min., respectively, over the catalyst to develop CNTs.

Arc discharge method for CNTs is carried out at elevated temperatures usually above 1000 °C. Cu and Ni containing carbon nanotubes were prepared by Saravanan *et al.* using DC arc discharge method [129]. Firstly, the graphite anode was filled with mixture of graphite and metal powder in the ratio 1:1. A graphite rotating disc with a speed of 8-10 rpm was used as cathode on which soot deposition occurred. The electric arc was generated *via* a DC source of 20 V and 150 A. Owing to high temperature and energy, vaporization of graphite and metals in air took place. The graphene sheets rolled into CNTs due to elevated temperature and enormous energy while the metals upon condensation deposited in the inner walls of CNTs. The CNTs so formed were washed with distilled water and dried. Finally, treatment with toluene for 5 hours and annealation for an hour at 650°C led to metal encapsulated CNTs.

Laser ablation technique is primarily used to prepare single-walled CNTs (SWCNTs). But nowadays multi-walled CNTs (MWCNTs) are also prepared by this technique. Recently, Ismail *et al.* have demonstrated fabrication of MWCNTs using pulsed laser ablation method in aqueous medium [130]. In this method high grade graphite pellet was placed in the glass cell filled with double distilled water.

The laser beam from Q-switched Nd:YAG of two wavelengths: 532 and 1064 nm with pulse width of 9 ns were focused on the graphite target by using positive lens of focal length of 5 cm. The ablation time and laser repletion rate selected for the process were 30 min and 2 Hz, respectively. The ablation cell rotated during the ablation process by using DC motor with 25 rpm and was used to prevent the vapour from depositing on the lens. Finally, colloidal CNTs were collected in the glass cell. Thus, MWCNTs with diamond like structure were formed.

Electrolysis of carbon materials in molten salts are widely used to prepare CNTs. Thin walled CNTs from CO_2 using molten carbonate was prepared *via* electrolysis by Wang *et al*. [131]. Electrodes (Muntz brass sheet-cathode and Nichrome-anode) were immersed in a mixture of electrolytes (lithium carbonate, lithium oxide, calcium oxide, and boric acid) and a constant current of 0.1 A/cm^2 was applied for 4 hours. The electrolysis temperature was 770 °C and impure sample was collected at cathode which was later washed. The washed product was recovered by vacuum filtration and dried overnight at 60 °C to obtain pure CNTs. The method resulted in ultra-thin walled CNTs (22–42 nm diameter) consisting of about 25 concentric, cylindrical graphene walls.

Sonochemical treatment of carbonaceous materials also results in CNTs. For instance, Wang and his research group have developed CNTs from graphene oxide *via* ultrasonication method [132]. The method involved dispersion of graphene oxide into HNO_3 solution (70%) which was subjected to sonication in ultrasonic bath at ambient temperature for 4 hours. Thereafter, water was poured into the suspension and centrifugation was carried out at 15,000 rpm to obtain CNTs. The CNTs were further purified their dispersion in water followed by centrifugation at 12,000 rpm for an hour to obtain pure CNTs.

Nanodiamonds

Nanodiamonds are nanosized carbon particles with dimensions less than 100 nm and were first discovered in 1963 [133]. The nanodiamonds due to their remarkable features like high solidity, large surface area, chemical inertness, enormous strength, optical clarity, biocompatibility, and thermal conductivity are quite useful carbon materials and can be fabricated by diverse techniques [134]. Detonation, CVD, laser irradiation and high pressure-high temperature methods are commonly used strategies for nanodiamond synthesis.

A bulk production of nanodiamonds from tetryl, a low cost explosive, was demonstrated by Panich and co-workers [135]. The detonation method proceeded with pressing of tetryl or its mixture with TNT and RDX at 1000 to 2000 kg/cm^3 into a cylindrical disc of 60 mm diameter and 110 mm height to form an explosive charge. The explosive charge was kept in an explosive chamber in a plastic bag

and was detonated. Further, it was reported that after every fifth detonation the valve at the bottom opened and the diamond soot was washed off with water. The diamond soot was then filtered, magnetically separated and centrifuged to remove impurities. Then, the soot was dried and crushed to obtain nanodiamonds. Thus, it was elucidated that tetryl serves as an excellent explosive material for fabrication of nanodiamonds.

Recently, Tallaire and his research group have synthesized loose nanodiamonds by plasma-assisted CVD method [136]. The synthesis was carried out in a quartz bell jar microwave reactor. The plasma was generated by microwaves at 2.45 GHz in resonant cavity. The reactor operated using a mixture of gases ($H_2/CH_4/O_2$) along with high microwave energy to produce nanodiamonds which agglomerated on water cooled molybdenum holder exposed to plasma at 450-500 °C. The agglomerated nanodiamonds were then washed away by ethanol and collected in cavity of bell jar reactor. The nanodiamonds thus obtained by the CVD technique showed superior crystallinity and lower impurities, which make this method advantageous.

In another method, pulsed laser induced ablation was used for synthesis of nanodiamonds from graphite. Basso *et al.* reported that laser ablation of graphite with KrF excimer laser was carried out [137]. The graphite target was kept in vial made of glass filled with liquid nitrogen. The laser beam of 500 mJ energy was focused on the target. After completion of ablation, liquid nitrogen was evaporated and the nanodiamond powders were formed. Consequently, laser ablation process offered an inexpensive and controlled approach for nanodiamond synthesis.

High pressure and high temperature technique for fabrication of nanodiamonds from hydrocarbons has attained great significance nowadays. This is because this method affords nanodimensional diamonds with highest possible structural perfection and crystallinity. Ekimov and co-workers have recently synthesized nanodiamonds from adamantane under high temperature/pressure conditions [138]. The process was performed at 7.7 and 9.4 GPa pressure and temperatures at 300 to 1600°C. The adamantane sample pressed in the form of a disc of 5 mm diameter and 3 mm thickness was placed in a titanium capsule in Torrid chamber. The temperature was controlled using Chromel-Alumel thermocouple at <1350°C and tungsten-rhenium thermocouple at temperatures up to 1600°C. The thermocouple junction was held on the outer wall at the mid-height of the capsule. The high pressure/temperature treatment of adamantane caused carbonization of thus leading to formation of nanodiamonds. It was reported that at 7.7 GPa only diamond microcrystals were formed but on increasing the pressure to 9.4 GPa,

nanodiamonds were formed. Thus, high pressure conditions are very important for synthesis of nanodimensional diamonds.

Das and Saikia have highlighted a novel method of synthesis of nanodiamonds from low grade coal under ultrasound exposure [139]. In this method, coal (2 g) was added to 100 mL hydrogen peroxide solution in a Teflon beaker and exposed to ultrasound-waves for 3 hours. A senor probe was used to measure the reaction temperature. After 3 hours of exposure, the reaction mixture was filtered to remove sulphur and other mineral contaminants. The filtrate was then poured into a beaker full of crushed ice and neutralized. Then the neutral suspension was filtered *via* a polytetrafluoroethylene membrane (0.22 μm) and dialyzed for 5 days in a 1 kDa dialysis bag. Thereafter, the solution was concentrated in a rotator evaporator and collected. The nanodiamonds synthesized by this method were obtained as monocrystalline and polycrystalline carbon nanocrystals with 4-15 nm dimensions.

Carbon Nano-onions

Carbon nano-onions are concentric shell like nanostructures consisting of nested fullerenes. The carbon onions were discovered for the first time by Ugarte in 1992 [140] and ever since their emergence several methods have been developed for their synthesis. Some of these include arc discharge method, chemical vapour deposition, pyrolysis, laser technique and thermal treatment of nanodiamonds.

Alessandro and co-workers have demonstrated synthesis of carbon nano-onions by water based arc discharge method [141]. It was reported that in an electric discharge apparatus, two graphite electrodes (anode of 5 nm and cathode of 10 nm diameters) were immersed in water and a potential of 12 V and current 30 A were applied between them. This resulted in formation of a powder that was dispersed in water and floated or settled at the bottom in the beaker. The floating powder like sample was collected on a microscope slide, whereas the bottom sample was recovered by water evaporation at 80 °C. The samples were then subjected to ultrasonication in ethanol for half an hour at 100 W. Finally, annealation of the samples at 400°C in air resulted in carbon nano-onions free from amorphous carbon residues. Highly stable, polyhedral carbon nano-onions were obtained by this method.

CVD method was employed by Zhang and his research group to prepare carbon nano-onions [142]. The synthesis was carried out by decomposition of methane gas over Ni-Fe alloy based catalyst at 850 °C. The process yielded highly graphitic carbon nano-onions.

In another method, carbon nano-onions were prepared from waste frying oil by pyrolysis technique. Jung *et al.* pyrolyzed the oil using a cotton wick under stable air conditions [143]. Then, to collect the sooty material, a beaker was inverted above the flame and the powder was gathered by scrapping off the deposited material. Next, the soot was calcined at 900 °C for an hour in a muffle furnace which led to carbonization and graphitization of carbon nano-onions. The method thus offered an economical approach for preparation of carbon nano-onions for application in energy storage devices.

A laser ablation induced carbon nano-onions synthesis was demonstrated by Dorobantu and co-workers [144]. A pulsed laser from Compex Pro 205 (KrF) excimer laser with a wavelength of 248 nm, pulse length of 25 ns and repetition rate of 10 Hz was used. The laser beam was focused on a pure graphite target under an ambient pressure of 7 Torr. During the process argon gas flowed at about 300 L/h through the reactor and temperature was maintained at 900°C. The ablation products then condensed on the water cooled cold finger to finally obtain the carbon nano-onions. The carbon nano-onions formed by this technique were about 10-25 nm in diameter.

Recently, Bartolome and Fragoso have reported synthesis of carbon nano-onions *via* thermal annealing of nanodiamonds [145]. The method involved annealing of 300 mg of nanodiamond at 1200°C at a heating rate of 50°C min^{-1} under argon atmosphere for 6 hours. Thereafter, the annealed sample cooled down to room temperature and a portion of this sample was then treated with 30% H_2O_2 for 3 hours, washed and dried to obtain pure carbon nano-onions. The protocol afforded carbon nano-onions with a diameter of 3-4 nm and comprising 5-6 graphitic shells.

Graphene and Its Derivatives

A multitude of top-down and bottom-up strategies for fabrication of graphene and its derivatives are reported in literature. These methods have been described in detail in Chapter 3.

SCOPE OF CARBOCATALYSTS

As mentioned earlier the carbon materials due to their several interesting properties find applications as catalysts in various fields such as environmental remediation, solar cells, fuel cells, energy devices, water splitting, redox reactions, sensors, biocatalysis, synthesis of fine chemicals, *etc*. For instance, Christoforidis and co-workers have lately reported the use of carbon nanotubes supported on graphitic nitride as photocatalyst for hydrogen production [146]. It was elucidated that the carbon nitrides functionalized with SWCNTs were found

to be about 2-5 times more efficient in catalyzing hydrogen evolution as compared to DWCNTs (double-walled carbon nanotubes) and MWCNTs under both the illumination of solar as well as visible light. This was attributed to the fact that CNTs worked as acceptors of electrons and further it was reported that the charge transfer varied inversely with the number of walls in CNTs. Thus, the transfer of photogenerated electrons occurred more readily when SWCNTs were used, thereby promoting H_2 production by providing more electrons.

Removal of pollutants from environment is a big concern and nowadays carbon catalysts are being widely used to remediate environment. Pausova *et al.* have recently employed active carbon (AC)-TiO_2 based composites as catalyst for photodegradation of benzoic acid in water and toluene in air [147]. It was reported that the incorporation of active carbon in composite enhanced photocatalytic activity due to greater adsorption ability of AC which facilitates adhesion of the pollutants. Further, it was also illustrated that the enhanced catalytic efficiency of AC was due to the milling process which increased its surface area thereby causing better adsorption of the substrates. Thus, active carbon based composites have merged as efficient catalytic systems for elimination of water and air pollutants.

The high conductivity, surface property and high melting point of carbon materials favour their application as electrodes in solar cells and fuel cells. Recently, Don and his research group have demonstrated use of acetylene carbon black-graphite composite as electrode for dye sensitized solar cells (DSSCs) [148]. It was highlighted that the composite was prepared in different ratio of carbon black and graphite *viz.* 0:1, 1:0, 1:1, 1:3, and 3:1 and the highest conversion efficacy was found to 5.06% for DSSCs containing acetylene carbon black-graphite in the ratio 3:1 compared to conventional expensive Pt counter electrode. This was because the carbon black particles offered greater surface area for ekectrochemical reaction in DSSC. Further, it was elucidated that the incorporation of acetylene carbon black particles on graphite enhanced the electrocatalytic efficiency of triiodide ion reduction by enhancing the electric conductivity *via* linking of the graphite flakes. Thus, acetylene carbon black-graphite composite can be used as cost effective alternative to Pt counter electrode in DSSCs.

Similarly, Bhavani *et al.* have reported use of fullerene based electrocatalyst in direct alcohol fuel cells (DAFCs) [149]. They prepared bimetallic Pd-W nanoparticles anchored on fullerene-C_{60} catalyst (Pd-W@Fullerene-C_{60}) for electrooxidation of methanol and ethanol for DAFCs applications. It was reported that owing to large electrochemical surface area, excellent conductivity, high reproducibility and long standing durability, the electrocatalysts showed

enormous catalytic activity for oxidation reaction compared to monometallic catalyst and commonly used Pt/C catalyst. It was revealed that the remarkable activity of the catalyst for oxidation of alcohols in fuel cells was attributed to the synergistic relation between Pd-W nanoparticles and fullerene. The uniform distribution of nanoparticles on fullerene prevented their aggregation resulting in enhanced surface area and stability. Moreover, the outstanding electron conductivity of fullerenes contributed to the overall catalytic activity of the Pd-W@Fullerene-C_{60} electrocatalyst, making them highly suitable electrode material for fuel cells.

In recent past, Chen and co-workers have reported the use of PT-Ni nanoparticles decorated on carbon nanofibres (PtNi/CNFs) as potent electrocatalyst for water splitting [150]. The catalyst was fabricated by electrospinning technique and carbonization. The catalyst was used as electrode for water splitting. It was reported that for hydrogen evolution in acidic medium (0.5 M H_2SO_4), the electrocatalyst achieved a 10 mA cm^{-2} current density at low overpotentials of 34 mV and a Tafel slope of 31 mV dec^{-1} similar to that of commercially available Pt/C (20 wt%) electrocatalysts. In alkaline medium (1 M KOH), the PtNi/CNFs catalyst showed a low overpotential of 82 mV to attain a current density of 10 mA cm^{-2} a small Tafel slope corresponding to 34 mV dec^{-1}. In addition, the PtNi/CNFs also show good activity for oxygen evolution in alkaline medium displaying a small overpotential of 151 mV to reach a current density of 10 mA cm^{-2} and a Tafel slope at 159 mV dec^{-1}. In acidic medium, the PtNi/CNFs exhibited an overpotential of 451 mV and Tafel slope at 198 mV dec^{-1}. Thus, on the whole the PtNi/CNFs electrocatalysts showed tolerable electrocatlaytic activity for water splitting. The catalytic efficiency of the PtNi/CNFs was ascribed to the synergism which arises due to homogeneous dispersion of Pt and Ni nanoparticles on carbon nanofibres, elevated conductivity of the nanofibres and three-dimensional interlinked frameworks of the carbon nanofiber mats. Consequently, carbon nanofibres have surfaced as significant electrocatlytic material for water splitting.

Owing to the extraordinary electrochemical properties of carbon nanomaterials, they have become a commonly employed as sensors. Mohapatra and his research group have designed carbon nano-onions (CNOs) as electrochemical sensor for detection of glucose [151]. The carbon onions were obtained by combustion of natural oils and a hybrid nanocomposite bearing CNOs, Nafion and glucose oxidase enzyme was fabricated to be used as sensor. The enzymatic CNO composite displayed good sensitivity of 26.5 μA mM^{-1} cm^{-2} with 0.21 mM detection limit. Non-enzymatic CNO nanocomposite bearing Pt nanoparticles were also fabricated which showed superior sensitivity of about 21.6 μA mM^{-1} cm^{-2} and a lower detection limit of 0.09 mM than enzymatic CNOs for detection

of glucose. The good sensitivities of CNO based nanocomposites were attributed to due to the high surface area, excellent conductivity and catalytic behaviour of CNOs. Overall, the research findings highlighted that CNOs serve as facile, economical and effective carbon materials for development of glucose detecting sensors.

The immobilization of enzymes on carbon materials has resulted in a new class of biocatalysts which is used for various purposes such as biosensing [152], removal of pollutants [153], dye degradation [154], synthesis of organic compounds [155], *etc*. In a study carried out by Wang and co-workers a lipase-immobilized carbon nanotubes were reported as biocatalyst for production of biodiesel [156]. The multiwalled carbon nanotubes bearing *Candida antarctica* lipase B were designed by pickering emulsification method. The prepared biocatalyst was then used to manufacture biodiesel from *J. curcas* L. seed oil. The esterification and trans-esterification of *J. curcas* L. seed oil with methanol in presence of biocatalyst resulted in 95.2% yield of biodiesel in 11 hours and 6 seconds at low temperature of about 35 °C. Thus, the liapse immobilized MWCNTs showed excellent biocatalytic activity. Moreover, the study revealed that the use of MWCNTs provided stability to the enzyme as well as rendered the catalyst recyclable up to 10 runs without significant loss in catalytic performance. Hence, it can be concluded that use of carbon nanostructures in biocatalytic systems can add features such as enlarged surface area, thermo-chemical stability, conductivity and mechanical properties which are beneficial for catalytic materials.

Over the past few decades, the carbocatalysts have been extensively used for chemical transformations. Recently, Dam *et al*. have employed graphite oxide as a heterogeneous catalyst for synthesis of pyrimidines [157]. The pyrimidine derivatives were afforded from one pot reaction between 1 mmol each of substituted benzaldehyde/heteroaldehyde, dimedone and 2-amino-benzothiazole or 2-amino-imidazole under solvent-less condition in presence of graphite oxide (20 mg) at 60 °C. It was also revealed that the catalyst generated good yields in short time and was reusable for 9 cycles. The use of graphite oxide carbocatalyst offered several advantages such as efficient reaction, easy recovery, high recyclability of catalyst, facile work-up and inexpensive synthetic protocol with avoidance of toxic solvents and metal based catalyst.

Considering the above examples it is clear that carbon materials exhibit wide range of catalytic applications. The broad scope of carbocatalysts cover diverse spheres including photocatalysis, electrocatalysis, biocatalysis and heterogeneous chemical catalysis owing to their merits such as interesting surface features, porosity, thermal conductivity, stability and electrical properties. Moreover, the

sustainability factor due to their renewability also renders carbon materials as suitable catalytic materials.

CONCLUDING REMARKS

Carbon and its allotropes are incredible materials that have been an integral part of chemical and physical sciences for ages. The extraordinary surface properties, conductivity, chemical inertness and renewability of carbon materials have turned them into sustainable catalytic systems. Ever since the first use of activated carbon as a catalyst for oxidation reaction, there has been a continuous development in the field of carbocatalysis. The diversely synthesized carbon materials with exorbitantly useful properties exhibit broad applications as photocatalysts for the removal of pollutants in the environment, sensors, heterogeneous catalysts for chemical syntheses, biocatalysts, and electrocatalysts in solar cells, fuel cells, water splitting, redox processes, *etc*. Consequently, the properties, synthetic methods and the scope of carbocatalysts have been highlighted in this chapter. The carbon polymorphs due to their unique surface characteristics and porosity have received immense attention as catalyst or catalyst support. The presence of large surface area and pores on carbonaceous materials facilitate the binding of substrates. Additionally, by suitable functionalization, doping or thermal treatment, the surface features and porosity of carbon facets can further be tuned to introduce beneficial defects which serve as active sites for reactant molecules. The emergence of nanodimensional carbon materials has also revolutionized the field of carbocatalysis because a reduction in size enhances the surface area which in turn improves their catalytic activity. Furthermore, the exceptional thermal conductivities and electrical properties of active carbon, graphite, fullerene, glassy carbon, carbon black, carbon nanotubes, carbon nanofibres, nanodiaomonds, carbon nano-onions, graphene and its derivatives have contributed enormously to their catalytic applications. The thermal conductivity and electrical property of a carbon material depend on the coordination and arrangement of C atoms as well as defects in the structural framework. By controlling the degree of carbonization or structural defects one can achieve desired properties in a carbocatalyst.

To realize the desirable characteristics of a carbon material, one needs a proper synthetic strategy. Diverse synthetic approaches for the synthesis of carbocatalysts have been described in this chapter. Active carbons are mainly procured by physical or chemical activation of raw materials like wood, coal, biomass, *etc*. The activation process governs the surface features and pores of active carbon. Graphite is a natural allotrope of carbon but synthetically it is fabricated by thermal treatment of coke or coal tar and hydrothermal treatment of polymers or metal carbides. The thermal treatment controls the graphitization

process. Nowadays, graphite encapsulated nanoparticles are also prepared by pyrolysis, template synthesis, chemical vapor deposition, arc discharge, laser ablation technique, *etc*. Fullerenes are macro-caged structures that are prepared by arc discharge, laser ablation and combustion techniques. Further, functionalization of fullerenes can also be carried out by sol-gel, solvo-thermal, chemical reduction, self-assembly, and ultrsonication techniques, to develop composites with catalytic properties. Glassy carbon electrocatalysts are fabricated by pyrolysis of polymers.

Besides, there are several thermal methods such as furnace black method, lampblack method, *etc*. for the preparation of carbon black particles of nanosize. Plasma synthesis has also been employed for the synthesis of glassy carbon composites. Chemical vapor deposition (CVD), electrospinning and template synthesis are commonly used strategies for the synthesis of carbon nanofibre based catalysts. Carbon nanotubes with relevant features can be synthesized *via* CVD, arc discharge, laser ablation, ultrasonication, electrolysis, *etc*. Detonation, high pressure-high temperature, laser irradiation and CVD are typical methods for the synthesis of nanodiamonds with exceptional surface, mechanical, electrical and thermal properties. Several bottom-up strategies including pyrolysis, arc discharge, CVD, laser ablation and thermal treatment of nanodiamonds are available for designing catalytic carbon nano-onions.

Considering the ever growing interest in carbocatalysis and the emergence of numerous fabrication strategies, it is evident that the field of carbocatalysts will continue to bloom in the coming days. However, there are certain concerns that need to be settled. The industrial scale syntheses of carbon based catalysts and their application need to be more cost-effective and feasible. The incorporation of desired properties using more benign methods also needs to be looked into. Further, identification of specific active sites on the carbon surface and detailed study of structural intricacies of carbon materials, thermal and electrical properties that essentially drive the catalytic behaviour of carbon catalysts also need to be dealt with at atomic as well as molecular levels. Overcoming these challenges will surely help in the expansion of the application spectrum and scalability of carbocatalysts.

LIST OF ABBREVIATIONS

AC	Active carbon
bcc	Body centered cubic
BET	Brunauer-Emmett-Teller
CVD	Chemical vapour deposition
CCVD	Catalytically-promoted chemical vapour deposition

CNF	Carbon nanofibres
CNO	Carbon nano-onions
CNT	Carbon nanotube
DAFCs	Direct alcohol fuel cells
DC	Direct current
DMF	Dimethyl formamide
DWCNTS	Double-walled carbon nanotubes
fcc	Face centered cubic
FTS	Fischer-Tropsch synthesis
MWCNT	Multi-walled carbon nanotube
N-CNOs	Nitrogen doped carbon nano-onions
NCNTs	Nitrogen doped carbon nanotubes
ODH	Oxidative dehydrogenation
ORR	Oxygen reduction reaction
PAN	Polyacrylonitrile
RBF	Round bottom flask
RDX	Research Department Explosive
RPM	Rotations per minute
SWCNT	Single-walled carbon nanotubes
TNT- 2	4,6-Trinitrotoluene

Abstract: Graphene is an allotrope of carbon that is made up of very strongly bonded carbon atoms. The structure of graphene is a hexagonal lattice. Graphene shows sp^2 hybridization and an extremely thin atomic thickness of approximately 0.345Nm. This chapter deals with graphene structure, including hybridization, critical parameters of the unit cell, the formation of σ and π bonds, electronic band structure, edge orientations, and the number and stacking order of graphene layers. The remarkable characteristics of graphene occur because of the extended chain of π conjugation that results in high charge mobility, high conductivity & high Young's modulus value. Due to these attractive properties, graphene has gained much attention. Graphene, with the unique combination of bonded carbon atom structures with its myriad and complex physical properties is balanced to have a big impact on the future of material sciences, electronics, and nanotechnology. Graphene is converted to Graphene nanoparticles, Graphene oxide nanoparticles; Polymer-based graphene composite materials and Graphene nanoribbons, *etc* by chemical methods. Some of the application areas are batteries and ultracapacitors for energy storage and fuel cell and solar cell for energy generation and some of the possible future directions of research have been discussed.

Keywords: Actuators, Application of Graphene, Chemical Properties, Electrical Properties, Electrochemical Capacitors, Fabrication of Graphene Oxide, Functionality and Solubility, Graphene Aerogels, Graphene Composites, Graphene Derived Nanofiller, Graphene Oxide, Hybrid Graphene, Mechanical Properties, Optical Properties, Properties of Graphene, Quantum Dots of Graphene, Storage Material, Surface-Enhanced Raman Spectroscopy, Thermal Properties.

1. INTRODUCTION

The 6th element of the periodic table *i.e*., Carbon has always attracted researchers and technologists and the most studied allotrope of the Carbon family is Graphene. It is a single atomic planar layer of graphite [1]. By chemical vapor deposition, chemical or mechanical methods, can be obtained from graphite [2, 3].

Theoretically, for the last sixty years, graphene or two-dimensional graphite had been studied [4]. Earlier, it was assumed that graphene does not exist in the free state. Peierls and Landau contended that since two-dimensional crystals were chemically not stable so they do not exist [5, 6]. Hence, it was proclaimed that graphene has large three-dimensional structures [7]. Without a three-dimensional base, two-dimensional structures do not exist, later in 2004, Novoselov *et al*. accidentally discovered graphene. Using a micromechanical cleavage technique single-layer graphene was established [8].

After several broadcasts on nanotubes of carbon (1991) [9], fullerenes (1985) [10], and intercalated graphite [11], graphene gained immense interest [12, 13]. It is a flat sp^2 hybridized planar sheet of C atoms densely packed in a 2D hexagonal pattern. It can be coated into zero-dimensional fullerenes, twirled into a one-dimensional nanotube, or can be bundled into three-dimensional graphite.

The uncommon characteristics of graphene involve that its charge carriers behave as Dirac fermions, and under encompassing situations they scatter. This distinct attitude resulted in exceptional phenomenal changes [12]. Firstly, it is a two-dimensional semiconductor with minimal overlapping between the conduction band and valence band and has a bandgap of zero. Secondly, for measuring deviation in room temperature (up to 10000 cm^{-2} s^{-1}) and charge carrier concentration (up to 1013 cm^{-2}) it shows a strong bipolar electric field effect. Thirdly, by modifying chemical potential with the help of the electric field effect, exceptional half-integer QHE for hole and electrons carrier can be seen [13, 14]. At room temperature, a single layer of a sheet, shows great thermal conductivity (5000 WmK^{-1}). Additionally, it's transparent with 2.3% absorption towards visible light [15, 16]. Transistors can be produced with narrower (1-2 nm thick) ribbons of graphene having variable band gaps [17 - 19].

In past years, graphene is being used instead of carbon-based nanofiller in preparing nanocomposites of polymer and showed great thermal, electrical, and mechanical properties [20 - 27]. Chemically unstable indium tin oxide in displays and screens can be replaced by graphene [28, 29]. Hence, it is assumed that a single layer is responsible for the uniqueness of graphene although its preparation is severe in encompassing conditions. Due to inappropriate separation of graphene

sheets, it aggregates and restacks leading to the formation of graphite *via* Vander Waals interaction and p–p stacking [30, 31]. Graphene has vast applications in the fields of microwave absorption shields, nanocomposites of polymer, super-capacitor devices, drug delivery, biosensing, *etc*.

According to IUPAC, graphene can be explained as a single sheet of C with a graphitic structure and similar to a polycyclic aromatic hydrocarbon. During a discussion of various properties of monatomic sheets, graphene is prescribed [32, 33]. In 1987, for the first time, the word "graphene" was used by Mouras *et al*. [34], although in 1840 Schafhaeutl (German scientist) narrated the exfoliation and intercalation of graphite by making use of HNO_3 and H_2SO_4. From that time researchers predict the presence of graphene. But it was not until 2004 that two physicists at the University of Manchester, Andre Geim and Konstantin Novoselov, obtained graphene in the laboratory and could prove it. These researchers developed an easy procedure for obtaining graphene from graphite. Using tape, a thin sample of graphite was extracted from a greater one.

This procedure was repeated several times to finally obtain a monoatomic layer, which was then electrically isolated with a thin layer of silicon dioxide on a silicon wafer. The importance of this event lies in having isolated graphene at room temperature since in the past this material was considered thermodynamically unstable. For their innovative experiments, in 2010 they received the Nobel Prize in Physics [35].

The important discoveries of a few scientists have been summarized below (Table **1**).

Table 1. Scientists with their discoveries.

S.No.	SCIENTISTS	DISCOVERIES
1.	Schafhaeutl (1840)	Narrated exfoliation and intercalation of graphite by making use of HNO_3 and H_2SO_4.
2.	B.C. Brodie (1859)	First discovered graphite oxide properties [97].
3.	Brodie, Staudenmaier, Hummers and Offeman (1958)	First synthesized graphene oxide through graphitic oxidation [109 - 111].
4.	Mouras *et al*. (1987)	For the first time, used the word "graphene" [34].
5.	Andre Geim and Konstantin Novoselov (2004)	Fabricated graphene from graphite in the laboratory and received Nobel Prize in Physics (2010) for this.
6.	Novoselov *et al*. (2004)	Discovered graphene using a micromechanical cleavage technique [8].
7.	Wu *et al*. (2011)	Established remote control graphene-based robot in the presence and absence of IR radiations [89].

2. FABRICATION OF GRAPHENE

2.1. Bottom-up Method

Various synthetic criteria can be used to prepare graphene and its derivatives but usually bottom-up and top-down methods are used (Kim, 2010a). From the past ten years, productive work has been done for the advancement of bottom-up criteria to atomically brief graphene nanoribbons [36, 37]. Usually, chemical and epitaxial methods are used to generate large-sized, defect-free sheets of graphene in minimal quantities. With the help of the CVD method's low resistance, monolayered graphene films (30-inches) had been produced having higher potential and great optical transmission properties replacing commercially available transparent electrodes (Bae, 2010). They have useful applications in electronic and fundamental fields but are inapplicable in the case of nanocomposites of polymer since they require altered surface graphene sheets. By selecting the starting material of nanotubes size can be controlled by unzipped graphene ribbons but preparing composites of polymer is still an expensive procedure.

2.2. Top-down Method

In this method, graphene is prepared by the exfoliation of graphite and its derivatives. Since globally graphite is produced in bulk (1-2 million tons per annum) so starting from it (like from graphite oxide) is favorable and economically more advantageous than a bottom-up approach.

3. STRUCTURE

Carbon has six electrons in total, out of which four are in the outer orbit and two in the inner orbit. Outer four electrons are capable of forming chemical bonds but in graphene, one C atom is attached to three C atoms in a 2-D plane leaving one electron free for electronic conduction. Such movable electrons are known as pi (π) electrons present above and below the plane and their overlapping boost C-C bonding (Fig. **1**). It also governs the electronic properties of graphene and in general, these properties depend on the bonding and anti-bonding of this π orbital.

Graphene has a 2D structure (of monatomic thickness) and is formed by a regular honeycomb network of joined C atoms. The bond length of the C-C bond is about 0.142 nm. The interplanar distance of graphene sheets is 0.335 nm which further stacks and leads to the formation of graphite. It is light with 0.77 mg /m^2 surface density.

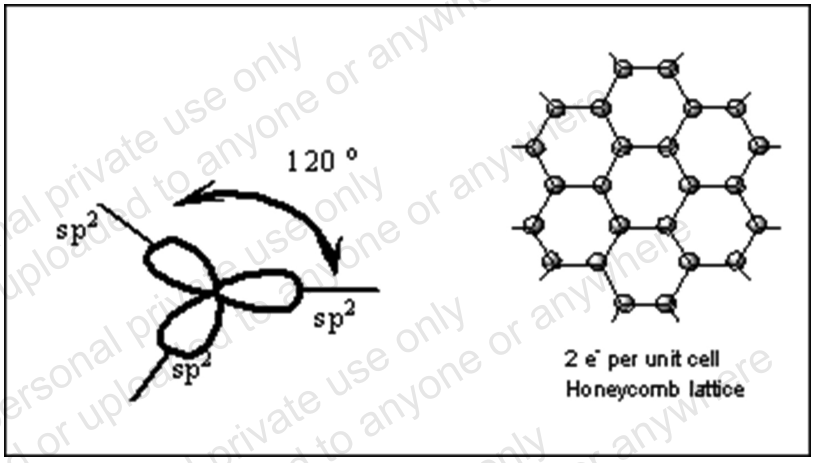

Fig. (1). Structure of graphene.

It is sp^2 hybridized and 0.345 nm thick. Since it shows normal electronic spectra, they are regarded as zero-band gap semiconductors. They can be rolled into a one-dimensional nanotube or in three-dimensional graphite. Its preparation is severe in encompassing conditions due to inappropriate separation of graphene sheets; it aggregates and restacks leading to the formation of graphite *via* Vander Waals interaction and p–p stacking [38, 39]. The aggregation *via* large-size or polar-polar interaction can be prevented if hydrophilic or hydrophobic groups are present [40].

Graphene can spontaneously repair voids present in its film when exposed to carbon-containing molecules [41]. Graphene sheets can be used to form other more complex carbon structures [42], like buckminsterfullerene, *etc*.

4. PROPERTIES

Due to its monatomic layer as well as the nature of the covalent bonds that can be extended making it no longer remain on the same plane, graphene is very flexible. Furthermore, it can be stretched up to 20% size [43].

The specific heat of graphene cannot be measured directly and is identical to that of graphite from 100 K, while for low temperatures graphene exceeds the contribution of phonons (vibrational modes of the crystal structure) of low frequency. At high temperatures, the specific heat is almost constant, approaching 25 $Jmol^{-1}K^{-1}$ (Dulong-Petit limit) [44].

Another feature to note is its impermeability to aqueous solutions, vapors, and gaseous medium, along with He (the smallest radius atom, 32 pm). However, it has been observed that water passes through the membranes of graphene [45].

Since graphene is flexible so it can be used in roller ball computers, heat-sensitive clothing, and flexible phones. It has a tendency of conducting electricity that's too better than Cu which is a boon to electronic applications for the next generation. It is transparent and thin (one-atom-thick *i.e.*, one million times thinner compared to a human hair). Graphene is associated with various properties shown in Fig. (**2**).

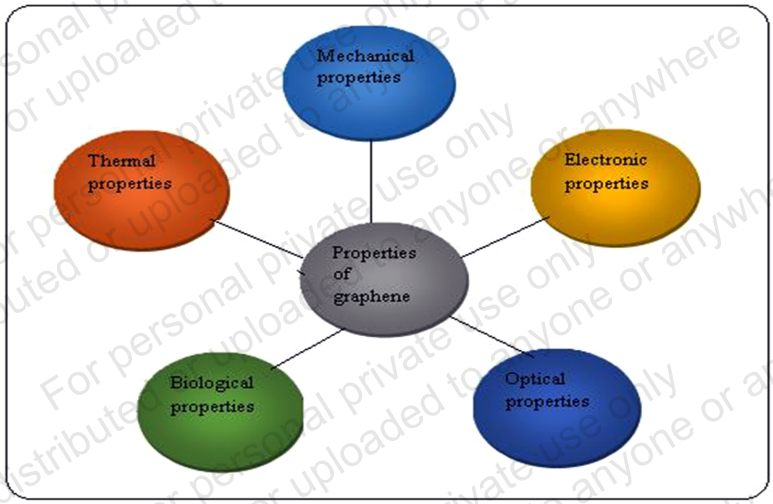

Fig. (2). Properties of graphene.

4.1. Electrical Properties

The symmetry & 2-D structure of graphene makes it interesting for research. It is illustrated as a zero-band gap semiconductor because, at the Brillouin zone's area, the meeting of its conduction & valance bond takes place. The charge carrier in graphene acts as relativistic or mass-less particles [46]. An ambipolar effect of the electric field is exhibited along with high concentrations [1013 cm^{-2}] in between electrons and the holes and have current mobility up to ~15000 $cm^2/(Vs)$ with interaction and electrical conduction between the substrate and the layers of graphene.

4.2. Mechanical Properties

Frank and his co-workers firstly reported the mechanical property of graphene. They used an atomic force microscope and calculated the spring constant. The

young modulus was found to be 0.5TPa and the spring constant between 1-5 N/m. Graphene is a highly used compound in the world. Graphene is a hundred times extra influential than steel and is harder than diamonds. Few mechanical properties include Poisson's ratio, tensile strength, and young's modulus. The mechanical conception should be placed in the continuous standard structure. Using a hypothesis, one can calculate its thickness. Graphene consists of a single layer of C atoms that makes its mechanical properties more significant. By using a traditional microscope or technique, it is hard to get efficient mechanical property while doing experiments because of its two-dimensional nature. So, for this, a new arrangement called atomic force nanoindentation has been achieved [47]. Generally, graphene is used to improve the mechanical properties of composites of polymer.

4.3. Thermal Properties

It generally causes vibrations that are created by the layered structure of graphene. Based on the dispersion curve of acoustic phonon & optical phonon, generally, six categories of polar phonons are recognized. These are the following [48]:

1. ZA mode phonons [Out of plane acoustic phonons] & ZO [optical phonons].

2. TA mode phonons [In plane transverse acoustic phonons] & TO [transverse optical phonons].

3. LA mode phonons [In plane longitudinal acoustic phonons] & LO [longitudinal optical phonons].

Currently, the most commonly used thermal conductive materials are copper, aluminum foil, carbon nano tubes, *etc*. Copper shows thermal conductivity of 380 W/mK, conductivity shown by Al foil is $160Wm^{-1}K$. Thermal conductivities of single-walled CNT & multiwalled carbon nano-tubes are $3500Wm^{-1}K$ and $3000Wm^{-1}K$ respectively. Diamond has the thermal conductivity ranging from $1000\text{-}2200Wm^{-1}K$ while that of single-layer graphene is $5000\ Wm^{-1}K$ [49].

Interplanar heat transfer processes within the two-dimensional plane of graphene are among the highest for known materials. It has been reported a value of $(4.84 \pm 0.44)103$ and $(5.30 \pm 0.48)103\ Wm^{-1}K^{-1}$ at ambient temperature, significantly higher than other carbon structures [50]. Processes for heat transfer perpendicular are to the plane; weak Vander Waals interactions limit the thermal conductivity. An approximate value of $6\ Wm^{-1}K^{-1}$ has been measured [51]. But in any case, both the presence of a substrate and defects in the structure of the graphene, condition their thermal properties significantly.

4.4. Optical Properties

The optical and outstanding charge carrier characteristics make it interesting. Over a vivid range of wavelengths, monolayer graphene can pass on 97% of the total incident light [52]. As the layers of graphene increase, the optical imaging & absorption of light is also increased [53]. Modulators, charge injectors, IR detectors, and emitters can also be formed from graphene [54]. When the light gets absorbed on the surface of graphene, some electron-hole pairs are generated that are based on the density of holes & electrons. These pairs can combine again and again very quickly, but the internal or external field that is generated close to the graphene-electron boundary can separate them [55]. To develop bioimaging techniques, this property of recombining & separating is very useful. Graphene can be cut into nano-ribbons which can make it luminous [56 - 58]. The recombining characteristic of the electron-hole pair can also make graphene a photo-luminescent material. Graphene has several applications in biomedical imaging & magnetic resonance imaging due to its high charge mobility, photo-luminescence, and high light transmittance [59, 60].

4.5. Chemical Properties

Graphene, the only allotrope of C whose every atom present on the two sides is responsible for chemical reactions because it is two-dimensional. As compared to other materials present in the environment graphene consists of maximum no. of C atoms present on the edge and they show specific reactivity towards chemical reactions and defects within them increase their reactive power.

4.6. Biological Properties

Sanchez and co-workers described the biological properties and the toxicity of nanocomposites of graphene [61]. Bianco also described this property recently [62]. A brief discussion of the interaction of cells and biomolecules with graphene is focused here. The nanomaterials based on graphene show a different kind of interaction with RNA & DNA. So, it is very interesting to use it in RNA or DNA delivery & sensing. Graphene oxide has better adsorption for single-strand DNA than double-strand DNA. It protects adsorbed nuclide against nuclease enzyme [63 - 66]. In high ion concentrated solution at low ph, the adsorption for small oligomers is increased because of negative charge interaction between graphene oxide and DNA [67]. Titov and his workers used coarse-grained molecules simulation of lipids and estimated that functional & stable hybrid structures can be formed of graphene [68]. Although these simulations have to be supported by

some data from experiments. For understanding the interaction between graphene & lipid bi-layer in the membrane of a cell, these studies are significant as shown in Fig. (**3**).

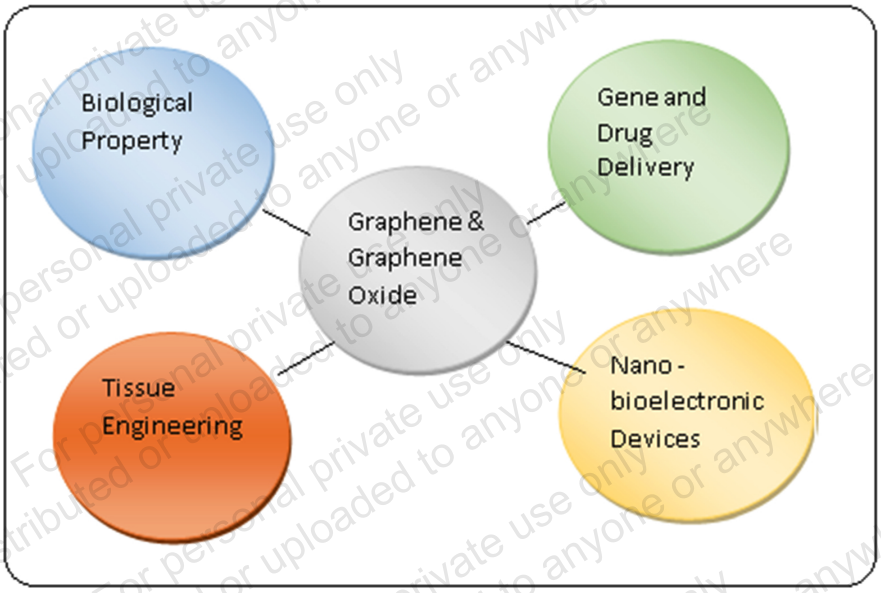

Fig. (3). Biological application of graphene.

Additional Properties

4.7. Functionality and Solubility

Graphene is insoluble in aqueous mediums like water, polymer resins. So, they require the attachment of some specific functional groups without affecting their physical and chemical properties. The functionalization of graphene has been carried out by different groups using various novel strategies [69]. Niyogy *et al*. *via* covalent bonding functionalized graphene [70]. To dissolve graphene in a non-polar solvent like CCl_4 and THF amidation was performed. When pristine graphene is treated with nitrating agents (sulfuric acid and nitric acid) it leads to the formation of aqueous graphene which remains stable for months. Si and Samulski performed a scalable and facile method to fabricate isolated, sparingly sulfonated liquid graphene [71].

Non-covalent bonding can also be performed for functionalizing graphene. This can be done by wrapping it with surfactants or *via* π-π bonding with aromatic molecules like PYBS [72]. This does not affect the electronic structure of graphene. When graphene is treated with surfactants like SDS and CTAB, it leads

to the formation of aqueous graphene or it can also be obtained by the interaction of acidified graphene with excessive PEG and concentrated hydrochloric acid under solvothermal conditions [73].

Liu and co-workers performed a single-step ionic liquid-aided electrochemical procedure to obtain ionic liquid functionalized graphene directly from graphite [74]. Here graphite works as cathode dipped in phase-separated water and ionic liquid (imidazolium-based) mixture with 10–20 V potential across electrodes. After half an hour graphitic anode produced ionic liquid functionalized graphene sheets with an average length of 700 nm and breadth of 500 nm. TEM images and AFM analysis confirmed the results.

4.8. Surface Area

Since graphene has a higher specific surface area and is highly porous, it makes it highly adsorptive for various gases like H_2, CH_4, and CO_2. Theoretically, the surface area of one graphene sheet is 2600 mg [75] but experimental results came around 270–1550 mg. Calculations performed using First-principle showed that carbon monoxide is present in a parallel configuration in hexagonal rings [75]. Calculations performed using First-principle showed that the hydrogen is present in parallel and perpendicular dimensions on cyclic rings of graphene and a single sheet of graphene use 7.7 weight% of H.

4.9. Fluorescence Quenching

Graphene is capable of light emission. It helps in the selective detection of biomolecules. This is directly linked with photo enhanced transfer of electrons. Quenching of porphyrin by graphene has been submitted [76].

Ramakrishna *et al*. worked on the light-emitting property of graphene [77]. During quenching of dye molecule when graphene was present, long-range energy transfer is considered.

4.10. Surface-Enhanced Raman Spectroscopy

SERS and simple Raman spectroscopy give almost similar information except that it provides enhanced signals. Fleischmann and co-workers (in 1974) enhanced a weak signal by introducing SERS [78]. After that, it came under focus and facilitates its identity in science. This enhancement effect follows two basic mechanisms *i.e*., electromagnetic enhancement mechanism (EM) and chemical enhancement mechanism (CM). The first one *i.e*., EM works based on exciting

surface plasmons while CM works based on the formation of a complex of the adsorbed molecule and its charge transfer. Experimentally separation of SERS and Raman spectroscopy is quite challenging. Preparation of SERS is done only in SERS research labs. By chemical reduction and electrochemical oxidation-reduction methods, active substrates of SERS can be obtained. Fabrication of nanostructures and nanowires too can be used as SERS substrates. After working on it, it was found that only "free-electron-like" metals *e.g*., silver, copper, and gold can be used as substrates for colloidal particles and rough surfaces. Limited substrates declined its applications. The SERS substrates are less biocompatible so, there is an urgent need to develop new ones. For an ideal SERS substrate, it should be cost-effective, easily accessible, biologically compatible, and chemically inert. Professor Ling and his co-workers reported the use of graphene as an efficient SERS substrate since it is chemically inert and biologically compatible. On depositing protoporphyrin IX, phthalocyanine (Pc), and crystal violate (CV) on the graphene surface, they found it useful as a substrate [79]. Further, the Raman Effect was examined on various layers and single-layered graphene was found to be most appropriate. With the increase in layers of graphene, the Raman signals decrease. The distance between the substrate and probe molecule should be lower than 0.2 nm in the case of the chemical enhancement mechanism. For transferring charge from molecules to metals and vice-versa the Fermi level of the substrate matches should be symmetrical to HOMO and LUMO of the probe. In the visible region, the optical transmission *via* the surface of graphene is greater than 95% and terahertz plasmon excitation. Because of these characteristics, it does not support the EM process. Now only CM is left for enhancing Raman signals. This is based on the fact that researchers worked on the possibility of charge transfer between molecule and graphene [80]. If graphene works as a SERS substrate, separation of CM and EM will be easily possible compared to other SERS substrates. Graphene can be easily synthesized, biocompatible, and cheap.

5. APPLICATIONS

Different types of applications in numerous fields associated with graphene as electronics, biomedicine, photonics, sensors and metrology, composites and coatings, generation & storage of energy, *etc*. shown in Fig. (**4**).

It possesses remarkable electronic properties and could replace silicon shortly by making use of itself in computer chips, ultrafast or quantum computers working at terahertz speed. Like photons, the electrons of graphene behave as massless particles. Unluckily, the complete study of electronic property is tricky.

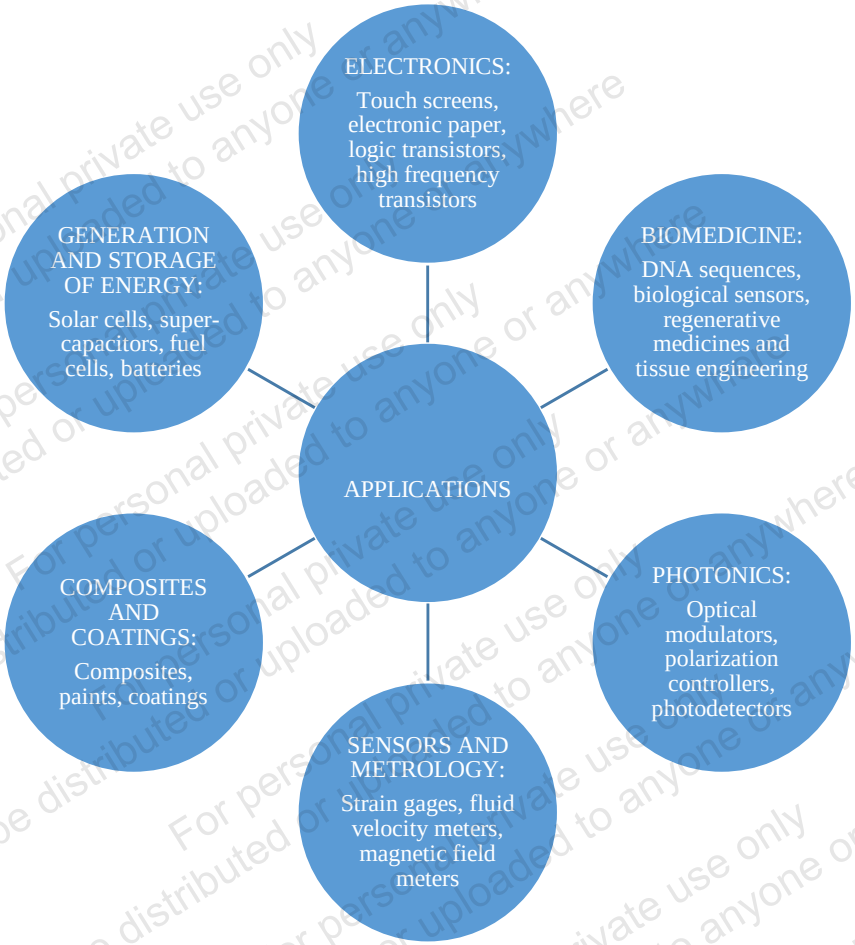

Fig. (4). Application of graphene.

Under the FET configuration, the transportation of electrons of graphene can be understood. FET is done by placing a sample of graphene on an oxidized silicon substrate and connecting it to the drain electrode and a source. The capacitance of the oxide layer is less than that of FET devices complicating the measurement of quantum capacitance.

The capability of a substance to store energy in the form of charge is known as capacitance. In physics, capacitance is resisted by electrically charged electrons. Although this capacitance is dominated by that of 2-D graphene. Pauli's Exclusion Principle explains quantum capacitance as a group of particles (which includes neutrons, electrons, and protons) that are unable to occupy the same energy stage at the same time. Only when an energy level is filled particles can excite to higher

energy levels. Xia *et al*. reported direct measurement of quantum capacitance of graphene in electrolytic ionic liquid media by making use of three electrodes of electrochemical configuration. It was published in Nature Nanotechnology in 2010 [81]. He attached two electrodes to graphene, and applied voltage across it with the help of the third electrode. The use of electrochemical gate and ionic liquid electrolyte reduced the Debye screening length to zero dominating quantum capacitance. The experimental data of Tao's experiment showed small graphene's capacitance. The plot of gate potential against quantum capacitance showed an asymmetric V-shape with a small Dirac point. This data grants theoretical prediction that signifies the quantum origin of interfacial capacitance in C-based electrodes.

The data provided by Tao declared the charged impurities are responsible for the declination of capacitance. This produces a low signal-to-noise ratio and found its application in chemical sensors and biosensors. The geometry of a single layer of graphene and low capacitance are boon to biosensors. By altering the electronic properties of the graphene, it can show when external biological substances interacted with the graphene layer. The study of antibody-antigen interaction by functionalizing the graphene's surface with antibodies can act as a useful application in biosensing. M. Shekhirev and co-workers reported that graphene nanoribbons having uniform electrical conductance can be produced on arbitrary high-temperature-resistant substrates, like metals, silicon dioxide, silicon, or its glasses, *via* the CVD method on basis of thermal decomposition of commercially accessible PTCDA molecules [82]. Polymer composites having a high thermal conductivity coefficient (λ) and excellent electrical and magnetic interference shielding efficiency have theoretical as well as potential practical applications [83, 84].

5.1. Storage Material

The energy density by mass of His high and that's why it is regarded as a basic carrier for energy. H storage is cost-effective and needs fast reaction kinetics, low adsorption temperature, high gravimetric and volumetric densities, and good reversibility. Since it is explosive so it requires stable storage conditions. It can be stored in solid materials (as adsorbed gas), pressurized cylinders (in gaseous form), and cryogenic liquid. The dissolution of hydrogen at high temperatures in metal hydrides is problematic so the chemical process is the safest method for storing H. Development in the field of nanomaterials can be useful because of the large surface-to-volume ratio and decreased diffusion path lengths of H.

Because of properties like high surface area, chemically stable and light graphene can be used. By chemical processes like chemisorption and physisorption, it can

be stored in graphene. Although practically it encompassed and normal temperature its storage is difficult. Therefore, to intensify the uptake of hydrogen C atom needs chemical modification. Palladium can strongly adsorb hydrogen and its role can be intensified three times under variable temperature and pressure. Graphene has a higher potential for storing H and can be used in fuel cell technology. Maidhily and co-workers made use of graphene for the proton exchange [85]. Subrahmanyam *et al*. reported the storage of H in graphene chemically [86].

5.2. Actuators

Researchers used the unique properties (optical, mechanical, and electrical) of graphene to study actuators. Park and co-workers prepared a bi-layer paper (graphene-based actuators) made of carbon nanotubes (multi-walled) and graphene oxide [87]. The curls of paper depend on temperature. Xie and co-workers by modifying two edges of a monolithic film of graphene with O_2 plasma and a six-membered ring prepared the surface asymmetrically graphene film actuator [88]. Based on graphene on organic hybrid film, a bimorph micro-actuator was established. It develops bending and capping motion that varies with frequency and potential. Wu and co-workers established remote control graphene-based robot. In the presence and absence of IR radiations, it can curl or uncurl [89]. It can pick and move any object in any direction. This is an exquisite manifestation of photochemical and thermal energy conversion by graphene-based actuators.

5.3. Electrochemical Capacitors

Nowadays, because of higher security, power output, fast charging and discharging efficiency, and ultra-long service life the electrochemical supercapacitors have been greatly advanced and contemplated as present generation devices [90 - 92].

They are also known as ultracapacitors/supercapacitors. They use fast surface redox reactions to store energy. In need of high-power delivery, they can replace batteries. A supercapacitor is high power and low-energy device and is useful in high-power pulse needs. They have a long-life cycle and higher power density and fill the space between dielectric capacitors and batteries. There are three types of supercapacitors divided based on conducting polymers, transition metal oxides, and C-C based. For higher capacitance blocking and electronically conducting electrodes are being used. Graphite-based carbon is electrochemically stable, highly conductive, and porous. The most used electrode material is activated

carbon since it is cheaper, capable, and has a high surface area. Graphene-based materials like fullerenes (0D), carbon nanotubes (1D), graphene (2D), and graphite (3D) are in focus because of their unique properties and structure. Since carbon nanotubes possess high electrical conductivity and surface area so they are being synthesized for supercapacitors. Although, CNT-based supercapacitors do not meet expectations but even after those experiments are being performed to improve their performance by growing them directly on bulk metals to remove resistance [93]. For supercapacitor applications, the graphene-based electrode material is being used [94] and on studying graphene supercapacitor, data revealed specific capacitance of 135 Fg^{-1} in aqueous electrolyte [95] and 117 Fg^{-1} in aqueous H_2SO_4 [94] on basis of multi-layered graphene. The effective surface area of graphene depends on the layer. So, graphene possesses high supercapacitor performance and surface area. Wang and co-workers [96] synthesized graphene-based supercapacitors and examined them. At room temperature, by the usage of gas-based hydrazine reduction of a single layer of graphene was performed. It showed low aggregation as compared to chemically modified liquid graphene. The capacitance of 205 F g^{-1} at 1.0 V in an aqueous electrolyte with an energy density of 28.5W h kg^{-1} has been observed and is the best data till now. Further, its power density was found to be 10 kW kg^{-1} greater than carbon nanotubes-based supercapacitors.

Poly pyrrole, polyaniline, polythiophene, and their derivatives are examined for supercapacitor electrodes. Wang and co-workers employed *in-situ* anodic electro-polymerization to synthesize flexible and free-standing graphene composite paper [96]. This paper electrode uses graphene sheets as building blocks having a tensile strength of 12.6 MPa and 233 F g^{-1} gravimetric capacitance and 135 F cm^{-1} volumetric capacitance respectively. This data is excellent as compared to other carbon-based flexible electrodes.

6. GRAPHENE OXIDE

6.1. Fabrication of Graphene Oxide

B.C. Brodie first discovered graphite oxide properties [97]. Although graphene oxide is synthesized by the treatment of graphite with strong oxidizing agents still it requires a reduction step which can be thermal or chemical to attain the properties of graphene.

The surface of GO was investigated under STM to obtain information regarding its structure [98, 99]. Due to bulky oxygen-containing functional groups, the width of the mono-layered graphene sheet is more than ~ 0.34 nm of ideal mono-layered graphene. Mono-layered graphene oxide has a width of ~ 1 nm; double-

layered has ~ 2 nm. Although their width varies with the degree of oxidation [100 - 102]. Xue and co-workers synthesized 3D framework structures with reduced GO on melamine foam (MF) frameworks [103].

Graphene oxide can be used in the synthesis of the ER dispersed phase since it has reduced electrical conductance and great polarizable property because of functional groups present on edges and planes. Although it has poor stability of dispersion because of the restacking of graphene sheets and in turn constrains utilization in engineering fields.

Hong and Jang reported a solvent exchange method for dispersing graphene oxide sheets in Si to intensify of stable dispersion of graphene sheets in non-polar solvents [104]. Through the drying process, the sheets agglomerated and restacked. Hummers' method was used to synthesize graphene sheets primarily. While for type II, the graphene oxide mixture was first dispersed in alcohol along with Si oil, and then it was centrifugated. They get stable in Si oil resulting in immensely stable graphene oxide suspension. Even after three months span, no specific sedimentation was seen [105].

Fabrication of graphene oxide involves two methods *i.e*., bottom-up approach where molecules of carbon form pristine graphene, and the other one is a top-down approach where layers of derivatives of graphene are synthesized from C-source, generally from graphite [106, 107]. The bottom-up approach (like epitaxial growth on silicon carbide wafers, chemical vapor deposition, *etc*.) is found to be time-consuming and unstably scalable [108]. Therefore, top-down approaches are much preferable which initially supports the generation of graphene oxide and reduced GO. Brodie [109], Staudenmaier [110], Hummers and Offeman [111] first synthesized graphene oxide through graphitic oxidation *via* different procedures. Hummers and Offeman further worked on it and improved it by using potassium permanganate as an oxidizing agent instead of potassium hypochlorite and adding $NaNO_3$. Usually, Hummers' method is being used because it is scalable and safe for the generation of graphene oxide. Any fabrication process which alters or shows improvement is termed as the "modified Hummers' method" [112]. Usually, a C-source is kept into a protonated solvent (like H_2SO_4, PO_4^{2-}, *etc*.) in the presence of a strong oxidizer (like potassium permanganate). For removing metal ions from it, dilution is performed resulting in a yellow-brown solution followed by separation and addition of HCl. Lastly washing and centrifugation are performed to neutralize its pH.

It is altered according to the researcher's needs. The morphology of GO depends on the dimensions of the carbon source obtained through modified Hummer's method [112]. In other words, the dimensions of synthesized graphene oxide

sheets depend on the diameter of the graphite powder. Huang and co-workers fabricated nanoribbons by unfastening carbon nanotubes (multi-walled) [113]. To lower the C/O ratio of the product often graphite is oxidized before the fabrication of graphene oxide. Few researchers follow Kovtyukhova and his co-workers [114], who treat graphite powder in potassium persulphate and phosphorous pentaoxide before using Hummers' method [115 - 117]. Others alter graphite into expanded graphite by thermal treatment or exposure to strong oxidizing agents [118, 119]. The famous alteration of this method is the "improved Hummers' method". It removes $NaNO_2$ *via* the addition of PO_4^{2-} and $KMnO_4$. It provides GO powders with a higher degree of oxidation at ambient temperature conditions and without the evolution of any toxic gas [120]. Novel work has been reported regarding the fabrication of graphene oxide. Zhang and his co-workers fabricated large graphene oxide sheets with an average size of 108 μm *via* stationary oxidation method [121]. The GO prepared by Hummer's method is relatively smaller than its graphite source. For synthesizing graphene oxide flakes of relatable size and morphology to graphite, sulfuric acid and potassium permanganate are added "without external mechanical agitations" hence forming a symmetrical three-dimensional structure later converting it into enlarged graphene oxide through "mild agitation". Enlarged graphene sheets are beneficial to composite materials. Dong and his co-workers reported an explanation for dispensable graphene oxide by forming GO slurries which could be scaled off and stored into flakes [122]. Single graphene oxide sheets bound *via* π-π stacking; although ion adsorption controls the aggregation of graphene oxide. By oxidizing their graphite pre-cursor and releasing it in a highly alkaline medium (pH 14), Vander Waals interaction is dominated by electrostatic repulsion hence, exfoliation leads to a slurry of low-viscosity instead of dispersion. It can be re-dispersed in N-methyl-2-pyrrolidone or alkaline medium, depicting a reliable method for storing and transporting graphene oxide flakes. Properties of graphene oxide and reduced form of graphene oxide given in Table **2**.

Table 2. Properties of graphene oxide and reduced form of graphene oxide.

Properties	GO	GO (in reduced form)
Fracture strength	120 MPa	-
Thermal conductivity	2000$Wm^{-1}K$ for pure 600W $m^{-1}K$ on Si/SiO_2	0.14-0.87W $m^{-1}K$
Electrical conductivity	10^{-1}S/cm	200-35000S/cm
Young's modulus	220 GPa	-
Optical transmittance	-	depends 60-90% on the synthesizing method and reducing agent

7. QUANTUM DOTS OF GRAPHENE

7.1. Fabrication of Quantum Dots of Graphene

Considering edge effects and quantum confinement of nano-graphene, its new derivatives have been evolved. Nanosheets of graphene having a lateral dimension below 100 nm and multi-layered stacks of graphene together are termed, graphene quantum dots [123]. Because of their flexible bandgap and fluorescence stability, they are of keen interest [123, 124]. Fabrication of these quantum dots requires alteration of graphene oxide and reduced graphene oxide *via* bottom-up and top-down approaches which include microwave-assisted thermal treatment, high-power ultrasonication, hydrothermal and liquid-phase exfoliation [125, 126]. Lu and co-workers reported the eco-friendly one-pot hydrothermal process for the fabrication of quantum dots (90 minutes) using black C [127]. By making use of H_2O_2 they can be made efficiently photo-stable and biologically compatible. Wang and co-workers demonstrated a single-step, one-pot hydrothermal procedure to fabricate quantum dots by making use of rice husk biomass. With the help of light-emitting quenchers, these quantum dots sensed iron's 3þ orbital [128]. A derivative of graphene is too diverse and involves varied fabrication processes and for fabricating graphene oxide, reduced graphene oxide, or quantum dots of graphene there is no “standard” procedure. It opens gates for many exclusive prospects.

8. GRAPHENE AND DERIVED NANOFILLER

8.1. Fabrication of Graphene and Derived Nanofiller

Because of the simple method of preparation, tunable property and wide application conductive polymer composites (CPCs) are of great interest (Fig. **5**). For synthesizing conductive polymer composites from non-conducting polymers, conducting fillers are inserted into them. They increase the conductivity of the material. This is known as an electrical percolation threshold (Pc). Both theoretically and experimentally it was found that with an increase in filler aspect ratio electrical percolation threshold decreases. So, by employing large aspect ratio conducting fillers conducting networks in a matrix can be synthesized [129]. Graphene composites possess great mechanical properties, extraordinary thermal conductivity, and higher electron portability at room temperature. For corresponding to electrical conductivity polymer composites use a 3D network. Wu and co-workers used a hot press method for the preparation of polystyrene composites having a three-dimensional network [130]. Chen and co-workers fabricated an excellent conducting composite film with the help of three-

dimensional graphene foam *via* template-assisted chemical vapor deposition method [131].

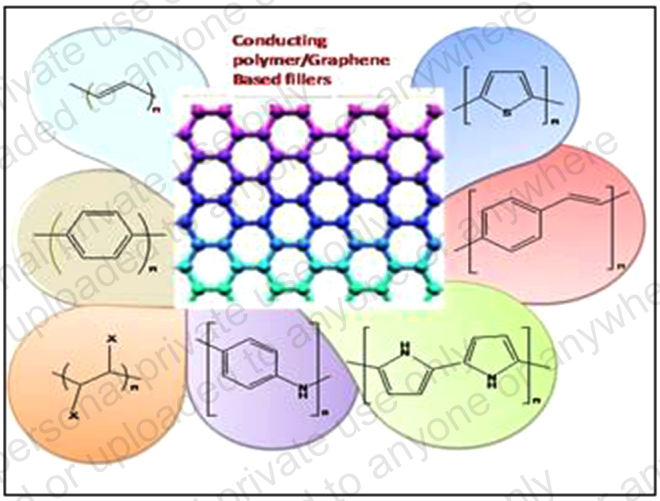

Fig. (5). Conducting graphene composite.

8.2. Significance of Graphene and Derived Nanofiller

As a nanofiller, graphene is preferred over other common nanofillers like exfoliated graphite, sodium montmorillonite, carbon nanotube, carbon nanofiber, and because of its higher aspect ratio, great surface area, low coefficient of thermal expansion tensile strength, electrical and thermal conductivity, transparency, flexibility, and shielding ability [132].

8.3. Application of Graphene and Derived Nanofiller in Energy and Electronics

Because of extraordinary microelectronic chips, high power densities they require conductivity issued as thermal pads, heat spreaders, and thermal interface materials. They are necessary compounds of thermal packaging and are responsible for maintaining a great relationship between metal sinks and chips [133]. The most important characteristic of graphene is modern electrical conductivity.

By inserting graphene into polymer matrix conductive polymer composites are being synthesized. Various polymers specifically polyvinyl chloride, polyvinyl alcohol, polymethyl methacrylate, polyethylene, polyamide, and polystyrene worked as matrices to fabricate graphene composites. They generally demonstrate

a non-linear improvement of the electrical conductance as a means of concentration of filler. They can be used to make sensors, solar cells, *etc*.

9. GRAPHENE AEROGELS (GAS)

It is a three-dimensional structure of graphene that produces porous and cheap structures of graphene. Various procedures including chemical-reduction methods [134, 135], hydrothermal methods [136, 137] Resorcinol (R), and Formaldehyde (F) sol-gel chemistry methods [138, 139] were suggested for the preparation of aerogels and monolithic aerogels on the basis of graphene oxide [140]. The chemical reduction method was found to be the most appropriate one since it is an eco-friendly and low-cost method. This method requires a low temperature without the need for a binder. Zhang and co-workers showed high electrical conductance of 102 S/m and a large surface area of 512 m^2g^{-1} was observed in synthesizing graphene aerogels through the chemical-reduction method [135].

10. HYBRID GRAPHENE/MICROFIBER COMPOSITES

An encouraging advance to ready graphene-based composites is by utilization of hybrid fillers that comprises an inorganic material and graphene-based materials. The hybrid combination gives an advantage such as synergistic effects between the fillers or final properties consequential from preservatives. The hybridization process will come across a few drawbacks of filler and progresses its interplay with the host matrix, it depends on its functioning criteria. Multifunctionality plays an important role in manufacturing composites (hybrid) since combined properties of diverse fillers correspond to a substance having a dissimilar set of characteristics as contrasted to characteristics of individually fabricated materials. In addition to this, the value of the ultimate product can be decreased by making use of fine microscale reinforcements like C and fibers of glass having lower levels of graphene where stress moves from micro to nano-scale reinforcement, hence improving the final properties.

Hybridizing graphene materials and the rest inorganic group showed outstanding properties at an atomic scale or nano or synergy can be exposed with complementarities. Hybrid graphene and other-two dimensional structures maintained the electronic properties and specifically, it can alter the bandgap of graphene. The zero-band gap of the unique graphene is unsuccessful in semiconductor materials; it is advantageous to its composites which can help in the manufacturing of graphene-based electronics. The addition of carbon to h-boron nitride increases electric conductance, which acts as an insulating agent in pristine form. The inductive band gap in graphene can effectively fabricate field-

effect transistors of graphene/ boron nitride films having 190-2000 $cm^2V^{-1}s^{-1}$ carrier mobilities. Cross-linking of graphene *via* chemicals and h-boron nitride composites could efficiently store energy. The (h-BN) Supercapacitors of graphene or boron nitride have B240 F/g specific capacitance. The bond formed between graphene and individual fillers affects the resulting physical and chemical characteristics of synthesized reinforced composites. To improve the efficiency amongst fillers various procedures were followed like solution blending, functionalization *via* chemicals, mechanical mixing, alternate growth, and many more. Aggregation of graphene takes place because of higher specific surface area and van der Waals interaction. The ornament of graphene is preferred since it avoids aggregation with other nanomaterials. Graphene's reactive sites got improved because of its functionalization which further improved its bond formation capability with the rest of the nanomaterials and finally led to the advancement of less significant covalent bonding between the matrix of host and hybrid-filler.

The functioning of multi-walled carbon nanotubes established effective bonds between multi-graphene platelets and fillers. The two-dimensional filler *i.e.*, multi-graphene platelets and one-dimensional filler *i.e.*, multiwalled carbon nanotubes combine to form a three-dimensional structure having a higher surface area. Thermal conductance of functionalized multiwalled carbon nanotube showed enlargement of >50% in comparison to pristine hybrid filler. Lin and co-workers accounted for the synthesis of Si/reduced GO hybrids through the electrostatic mechanism and then it is mechanical blending with BUNA-S (styrene-butadiene rubber) matrix. Great experimental distribution has been seen in hybrid materials in comparison to individual fillers having great matrix interaction.

11. GRAPHENE BIOACTIVE COMPOSITES

Various bio-sensors which depend on graphene for different sensing purposes consist of separate criteria for electrochemical and optical signals. Because of its quick response, elevated sensitivity, excellent electrochemical properties, straightforward operation, and low-cost graphene is used as a probable contender for biomolecule discovery. Zhou and co-workers examined the electrical and chemical activities of the graphene-modified electrode towards H_2O_2. In comparison to the exposed electrode, noteworthy enlargement in the rate of electron transmission of graphene-based electrodes has been obtained. Shao and co-workers accounted for superior electro-catalytic progress of (N-doped graphene) N-graphene towards reduction of H_2O_2 in comparison to graphene, responsible for the occurrence of N- containing groups, O- functional groups, and

structural defects. GO possess fluorescence over a broad array of wavelength *i.e*., 200 -1200 nm and it successfully quenched the light-emitting property of other fluorescing dyes.

12. CONCLUDING REMARKS

This 2D material which seemed to be of least research in past decades had now become a boon to society since it provides unique and reliable solutions to globally challenged environmental problems. In this chapter, we have briefly discussed its properties and application areas which makes it more content for scientists to depend on. The distinct and captivating properties of graphene make it unique in a way that could lead to substantial advancement in the near future. Its properties make it one of the most reliable materials in various applicable areas which include sensing, tissue engineering, electronics, *etc*. Although many interdisciplinary areas still seek its contribution in different ways which need to be discovered which will further accelerate a better understanding of graphene-based materials. Its properties have paced new ways for scientists working for the betterment of the global environmental progressions.

CONSENT FOR PUBLICATION

Not applicable.

CONFLICT OF INTEREST

The author declares no conflict of interest, financial or otherwise.

ACKNOWLEDGEMENTS

The authors would like to acknowledge Banasthali Vidyapith for providing an internet facility for the completion of this chapter. One of the authors Dr. Nirmala Kumari Jangid is thankful to Dr. Pinki Bala Punjabi and all editors for allowing her to write this chapter.

LIST OF ABBREVIATIONS

AFM	Atomic/Scanning force microscopy
BUNA-S	Styrene-butadiene rubber
CCl_4	Carbon tetrachloride
CM	Chemical enhancement mechanism
CNT	Carbon nanotubes
CPCs	Conductive polymer composites

Not be distributed or uploaded to anyone or anywhere For personal private use only

CTAB	Cetyltrimethylammonium bromide
CVD	Chemical vapor deposition
DNA	Deoxyribonucleic acid
EM	Electromagnetic enhancement mechanism
FET	Field-effect transistor
GO	Graphene oxide
HOMO	Highest occupied molecular orbital
IUPAC	International Union of Pure and Applied Chemistry
IR	Infra-red radiations
LA mode phonons	Longitudinal acoustic phonons
LO	Longitudinal optical phonons
LUMO	Lowest unoccupied molecular orbital
MGP	Multi graphene platelet
MF	Melamine foam
MWCNTs	Multi-walled carbon nanotubes
PC	Percolation threshold
PEG	Polyethylene glycol
PYBS	1- pyrenebutanoic acid succinimidyl ester
PTCDA	Perylenetetracarboxylic dianhydride
SDS	Sodium dodecyl sulfate
SERS	Surface Enhanced Raman Spectroscopy
STM	Scanning tunneling microscopy
TA mode phonons	Transverse acoustic phonons
TEM	Transmission electron microscopy
THF	Tetrahydrofuran
TO	Transverse optical phonons
TPa	Terapascal
QHE	Quantum Hall effect
RNA	Ribonucleic acid
ZA mode phonons	Out of plane acoustic phonons
ZO	Out of plane optical phonons
2D	Two-dimensional

For personal private use only Not be distributed or uploaded to anyone or anywhere

Abstract: Over the past few decades, graphene and its derivatives have carved a niche for themselves in material science. These carbon nanomaterials exhibit a broad range of applications owing to their enchanting features like high specific surface area, chemical inertness, astonishing electrical and thermal properties, elevated intrinsic mobility, inimitable optical properties, and huge mechanical strength. Considering the ubiquitous applications of graphene in different industries, diverse top-down and bottom-up methods have been developed. This chapter outlines the various methods used for the synthesis of graphene and graphene-based derivatives, such as exfoliation, unrolling or unzipping of carbon nanotubes, electric arc discharge method, laser ablation technique, oxidative exfoliation-reduction of graphene oxide, chemical vapour deposition, epitaxial growth, template synthesis, pyrolysis, substrate-free synthesis, total organic synthesis, and biological methods, highlighting the advantages of these methods. Upcoming challenges concerning the commercial synthesis of graphene have also been addressed in the concluding part.

Keywords: Bottom-up Strategies, Graphene, Graphene Oxide, Reduced Graphene Oxide, Top-down Methods.

INTRODUCTION

Graphene, a 2-D carbon allotrope, is one of the thinnest and strongest materials known. Graphene has a honeycomb lattice structure comprising a monolayer of sp^2 hybridized carbon atoms assembled as hexagonal rings [1]. In 1859, Brodie, while examining the structure of graphite for the first time, observed graphene and

coined the name "graphone" [2]. Later, Boehm *et al.* were the first to use the term 'graphene' [3]. For a long time since its first discovery, very little work has been reported on graphene. Then in 2004, Novoselov, Geim, and their research group isolated graphene from graphite with a simple exfoliation method [4]. The reinstating of graphene by Geim and Novoselov, who were awarded the Noble Prize in 2010 for their work on graphene [5], paved the way for "Graphene Science". Ever since then, a plethora of methods for the synthesis of graphene and its applications in various areas have been explored by researchers worldwide.

The incredible properties namely, enlarged specific surface area (up to 2630 m^2 g^{-1}), enormous intrinsic mobility (200,000 cm^2 v^{-1} s^{-1}), stupendous thermal conductivity (<5000W m^{-1} K^{-1}), extremely large Young's modulus (< 1.0 TPa), exceptional optical transmittance (< 97.7%), outstanding electrical conductivity, and tremendous chemical stability, displayed by graphene arise from its distinctive structure and arrangement of carbon framework [6 - 9].

The arrangement of mono graphitic lamellae of carbon particles in hexagonal planar sheet stacked in one or few layers forms bi-dimensional graphene. It has been reported that graphene lamella has a thickness of about 0.35 nm, comparable to 1/200,000th of the diameter of a strand of a human's hair [10]. The bi-layer and few-layer graphenes consist of two and three to ten layers of graphitic sheets, respectively. Graphene with twenty to thirty sheets is identified as multilayer or thick graphene or nanocrystalline thin graphite [11]. The monolayer graphene has a wavy sheet without any stacking. While, in the bi or few-layered graphene, the graphitic sheets are arranged in AA (hexagonal) or AB (Bernal) or ABC (rhombohedral) stacking [12]. Also, the few-layered graphene with no appreciable stacking order is commonly termed turbostratic [13].

The sp^2 bonding of carbon atoms in graphene exhibits three σ bonds (in-plane) formed by hybridization of s, p_x, and p_y orbitals and a π bond formed by p_z orbital perpendicular to the plane [10, 14]. The σ bonds form a firm backbone of hexagonal geometry, whereas the out-of-plane π bonds result in inter-lamellar interaction between graphene layers [10]. The existence of free electrons in the π bands is thus responsible for the exclusive electrical and optical properties of graphene [15]. Furthermore, the electrical conductivity of graphene is governed by the type of edges. Generally, armchair or zigzag edges exist in graphene. The variety and density of edges can generate metallic or semiconducting behaviour in graphene [16].

In spite of the desirable features of graphene, the lack of industrial-scale production is a major hindrance to its applicability in diverse fields. In such a scenario, the surfacing of graphene oxide and reduced graphene oxide has been a

relief for material chemists and industrial workers. This is because preparative protocols for GO and rGO are quite simple, require inexpensive starting materials, and result in mass production of these materials [17].

The oxidized form of graphene, *viz*. graphene oxide (GO), is structurally similar to graphene but with the presence of oxygen functionalities [17]. The precise structure of GO has been a highly controversial subject owing to its amorphous, berthollide character and hygroscopic nature [18]. Despite its debatable structure, several models have been proposed to elucidate the structural architecture of GO. Hofmann and Holst were the first to put forth a model suggesting that the epoxy groups exist at the basal planes of the graphite layer, with an overall molecular formula of C_2O [19]. Next, Ruess anticipated a model which elucidated that the carbon sheets were puckered instead of planar and the oxygen-containing groups like hydroxyl and ether-like oxygen formed bridges between the carbon atoms at positions 1 and 3 of the graphite framework [20]. Thereafter, Clause and co-workers [21], to explain the acidic nature of GO, further illustrated an enol- and keto-type model. In 1969, Scholz and Boehm [22] presented a novel arrangement of GO, which encompassed grooved carbon layers bearing hydroxyl and carbonyl functional groups. Nakajima and his research group [23, 24] also proposed a model elucidating the structural attributes of GO. According to them, GO comprises two carbon layers anchored to each other by sp^3 hybridized carbon-carbon bonds at right angles to the layers with the presence of relative numbers of carbonyl and hydroxyl groups based on the hydration scale. In 1997, Lerf and his colleagues [25] suggested the most widely accepted model for GO. As per their model, GO consists of haphazardly dispersed planar aromatic sections comprising un-oxidized benzene rings and crumpled zones of six-membered alicyclic rings with C=C, C−OH and ether groups at 1 and 2 positions [26]. Finally, Szabó *et al.* presented the most recent structural model for GO [27]. The model revealed that the carbon framework exhibits two kinds of zones, one with trans-linked cyclohexane chairs and the other one bearing ribbons of flat hexagonal rings with C=C bonds as well as functionalities, including tertiary OH, 1,3-ether, ketone, quinone, and phenol. Overall, it is clear that the structure of GO comprises graphitic regions, disordered oxidized areas, and regions with defects (which arise due to holes *via* the release of CO and CO_2 during the belligerent oxidation and exfoliation of the sheet in GO) [28].

Additionally, the partial reduction of graphene oxide restores the carbon framework of a graphene layer with the presence of a few oxygen functional groups. This form is known as reduced graphene oxide (rGO). The atomic structure of rGO was studied by Navarro *et al.* [29], and it was explicated that rGO sheets include large areas of undamaged graphene along with considerable regions rich in defects, namely, pentagonal-hexagonal pairs and planar, quasi

amorphous sp^2 bonded carbon clusters. It was reported that the defects occur due to imperfections in the crystallinity of graphene layers after GO reduction. Furthermore, through molecular dynamics simulations, it was revealed that carbonyl and ether groups are quite stable and hinder the complete reduction of GO [30]. Therefore, at low temperatures only, hydroxyl groups desorb without affecting the basal planes of graphene. While the more stable epoxy groups leave the GO surface at high temperatures, resulting in profound distortions in the graphene network. Thus, reinstating the extended π-conjugated network in rGO with some topological defects leads to superior electrical properties of rGO compared to GO. It is also noteworthy that owing to the existence of residual functional groups in rGO, the flow of charge carriers is disrupted *via* sp^2 networks, and thus, electric flow principally occurs by hopping, unlike graphene, where charge carriers flow ballistically [31 - 34]. Another feature of GO and rGO is hydrophilicity, which ascribes to the inclusion of functional groups that renders them soluble in water, organic solvents, and various other polar media [35].

Consequently, by fine-tuning the structural morphology, edges, number of sheets, defects, and functionalities in graphene or graphene oxide/reduced graphene oxide, one can realize desirable characteristic properties of graphene for diverse applications. To achieve this, one can adopt a cost-effective, reliable, simple, high-yielding, time-efficient, and scalable synthetic strategy for graphene synthesis. Considering the crucial inter-relationship between synthesis, property, and application of graphene, the chapter intends to highlight diverse top-down and bottom-up strategies available for designing graphene and its derivatives.

TOP-DOWN SYNTHESIS

Top-down methods are based on the breakdown of graphitic compounds into mono- or few-layer graphene [13]. The top-down approaches for graphene and its derivatives include exfoliation, unrolling or unzipping carbon nanotubes, electric arc discharge method, laser ablation technique, and oxidative exfoliation-reduction of graphene oxide.

Exfoliation Method

Exfoliation is the most cost-effective for the production of graphene from graphite. The process involves the un-stacking of graphite layers by increasing the inter-planar spacing *via* the breakdown of van der Waals forces and causing poor bonding in the direction orthogonal to the planes [36]. The exfoliation method is of two types: mechanical and chemical.

Mechanical Exfoliation

Mechanical exfoliation is also referred to as the "scotch tape" method. This is because in this technique, an adhesive tape is put on a graphite sample, and then the sample flakes are peeled off. The process involves preferential cleaving of flakes that stick to the tape along the crystal plane [37]. Furthermore, few- and single-layered graphene are obtained by pressing a fresh tape against the graphite flakes that adhere to the first piece of tape. Thereafter, the two tapes are peeled apart, slicing graphite into thinner sheets. By repeating the process several times, very thin graphite sheets are obtained [38]. In mechanical exfoliation, milling, stirring, ultrasonication or fluid dynamic techniques are employed to pull apart graphite layers [39].

For instance, Chen and co-workers have reported the synthesis of mono- and few-layer graphene using a three-roll mill machine and a polymer adhesive [40]. A three-roll mill with three adjacent cylindrical rolls (80 mm in diameter), which rotated at the same velocity, was employed, as shown in Fig. (**1**). The first (feed) and third (apron) cylindrical rolls moved in the same direction while the central roll rotated in the opposite direction. The mechanical force of the mill causes the S-shaped movement of the graphite sample in the rolls, causing continuous exfoliation of graphite. To prepare the polymer adhesive, poly vinyl chloride (PVC) was dispersed in dioctyl phthalate and magnetically stirred for half an hour. Then, the adhesive and graphite were placed in the mill. As the rolls rotated, the graphite sample gradually spread on the adhesive, followed by homogenous dispersion on the rolls and exfoliation of the graphite to form graphene. The process of exfoliation was performed for 12 h at ambient temperature. Finally, pure graphene was obtained by adding alcohol to impure graphene in order to remove dioctyl phthalate, followed by combustion in the muffle furnace at 500 ^{o}C for 3 h to burn PVC. The method offered a large-scale synthesis of homogeneous graphene sheets of a thickness of about 1.13-1.41 nm.

The use of acoustic cavitations for mechanical exfoliation of graphite flakes is also well known. The dispersion of graphite in suitable solvents like water, ethanol, DMF, *etc.* followed by ultrasonication leads to the breakdown of graphite sheets. The mechanism of ultrasonic exfoliation basically involves distribution of cavitation bubbles around the graphite flakes. The violent collapse of these bubbles generates shock waves which produce stress throughout the graphite material leading to splitting of graphite sheets. Additionally, the unbalanced lateral compressive stress may also separate two adjacent graphite layers by shear effect. The ultrasonic method offers low cost industrial scale production of graphene but sometimes it is deemed unfit because ultrasonic exfoliation in some cases results in fractures in graphene sheet and other undesirable defects.

However, by carefully controlling the reaction parameters like temperature, sonication power, solvent, and sonication time once can overcome this issue as well.

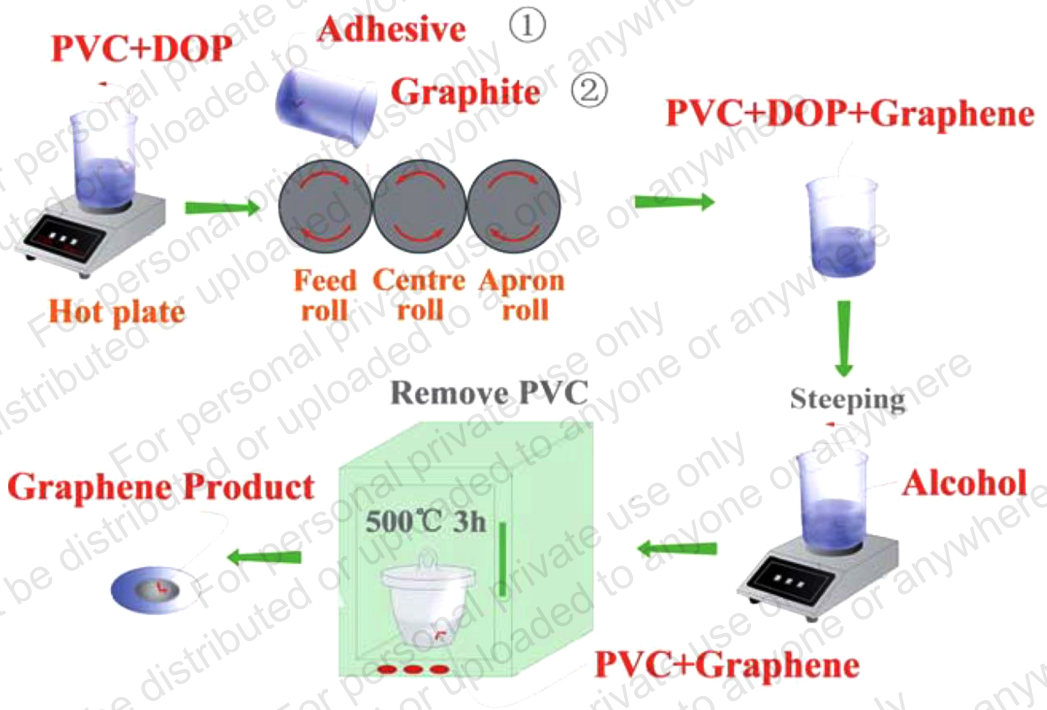

Fig. (1). The use of a three-roll mill machine for the synthesis of graphene by mechanical exfoliation. Reprinted with permission from [40]. Copyright 2012 The Royal Society of Chemistry.

Lately, Noroozi *et al.* demonstrated an ultrasonic exfoliation of graphite under environmentally benign conditions [41]. A mixture of polyvinyl pyrrolidone (PVP), hand soap-deionized water and graphite was stirred followed by sonication for 3 h. The reaction mixture was then kept still for 24 h leading to settling down of the large graphite aggregates at the bottom. A uniform dark suspension was obtained which was left undisturbed for five months. After that the suspension was washed with deionized water and centrifuged at 4,000 rpm for some hours which resulted in the formation of a gel like substance. The gel was dried overnight in a vacuum oven at 80°C followed by annealing at 1000°C for 5 min, to eliminate any residual PVP from the material. At last, pure few layered graphene sheets were obtained as black powder. Thus, graphene sheets were afforded by a low cost and simple sonication based exfoliation method.

Ball-milling of graphite for production of graphene has also gained much attention. Typically, two mechanisms are known for delamellation of graphite *via* ball milling [39]. In the first approach, shear force exerted for exfoliation is employed to produce large sized graphene flakes. The second approach makes use of the collisions or vertical forces applied by the balls in rolling actions to produce small flakes. Recently, Balasubramanyan and his research group have prepared graphene flakes using ball-milling technique for exfoliation [42]. A planetary ball-mill with 14 stainless steel balls was used for this purpose. In this method, sucrose and graphite were milled at 70 rpm for 30 h to obtain graphene-sucrose mixture. Thereafter, the mixture was calcinated for 3 h at 400 °C to obtain pure graphene. The method was high yielding and afforded graphene with fewer defects.

Nowadays, fluid dynamics methods are also employed for mechanical exfoliation. In this method, the graphite flakes flow with the liquid and are exfoliated frequently at different points [43]. An exfoliation method based on fluid dynamics was reported by Tran and his colleagues [44]. In this method, the Taylor-Couette flow reactor (Fig. **2**) consisting of two coaxial cylinders was used with a mixing vessel connected to a circulating chiller for prevention of heating up of the solvent.

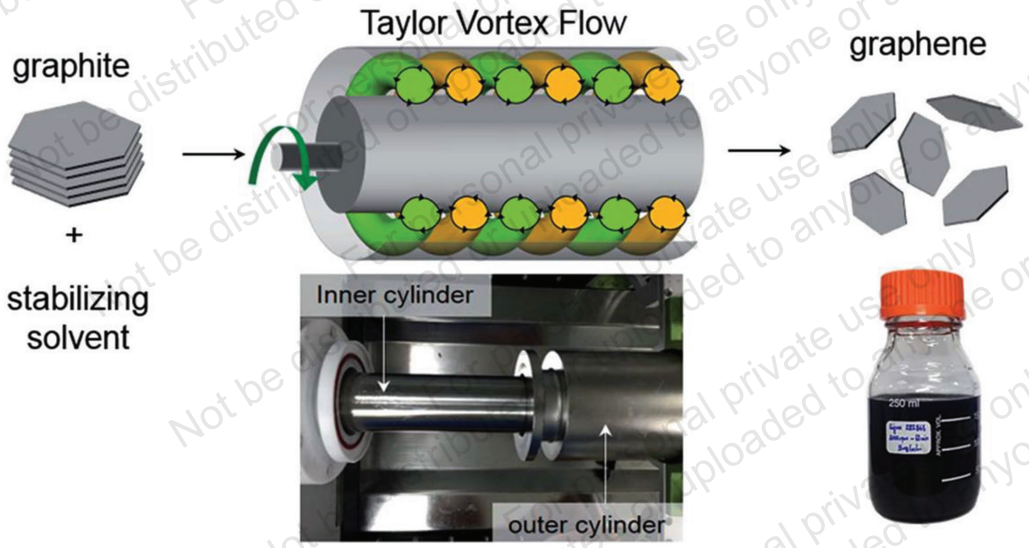

Fig. (2). Synthesis of graphene by using Taylor vortex flow. Reprinted with permission from [44]. Copyright 2016 The Royal Society of Chemistry.

The graphite powder and stabilizing solvents (N-Methyl-2-pyrrolidone and dimethylformamide) were injected into the space between the two cylinders of the

reactor. Then, as the inner cylinder of the reactor rotated at a speed of 500 to 3000 rpm for 10 to 120 min., shear mixing of graphite took place. The mixing resulted in the exfoliation of graphite and the resultant dispersion was centrifuged for half an hour at 1000 rpm to discard un-exfoliated graphite particles. Finally, exfoliated graphene was collected from the supernatant. The advantage of fluid dynamic method is that it affords high quality of graphene in short time.

Chemical Exfoliation

In chemical exfoliation, chemical agents are used to ablate graphite sheets. The chemicals first reduce van der Waals forces by increasing inter-layer spacing by intercalating themselves between the graphene layers. Then, thermal/high pressure treatment leads to breakdown of the intercalated graphite to form graphene [45].

Recently, a scalable fabrication of few-layer graphene by chemical exfoliation of graphite flakes has been demonstrated by Liu and his research group [46]. The process involved mixing of peroxyacetic acid with sulphuric acid followed by the addition of graphite to the binary system. The resultant mixture was stirred at room temperature to form a turbid liquid. During stirring, the decomposition of peroxyacetic acid took place accompanying oxygen evolution. Thereafter, the mixture was allowed to stand at ambient temperature and exfoliated graphene was obtained after 4 h. Pure graphene was obtained by filtration and washing with deionized water followed by air drying. In this method sulphuric acid intercalates between the graphite layers while the oxygen gas evolved by decomposition of peroxyacetic acid causes an increase in pressure that results in an increase in inter-layer distance to such an extent that van der Waals forces are conquered resulting in peeling off graphite layers to form graphene. This novel method produced graphene with an average of five layers.

In another chemical exfoliation method, microwave irradiation was used for rapid graphene synthesis [47]. The method involved two steps. In the first step, graphite intercalated with perchloric acid was prepared by mixing graphite with acid followed by 2 min. stirring under ambient conditions. Then, acetic anhydride was added to the mixture and the reaction mixture after stirring was subjected to microwaves for 30 s at 700 W resulting in $HClO_4$-intercalated graphite. In the second step, the intercalated graphite was suspended in deionized water and irradiated by microwaves for 80 s. This process led to large expansion of intercalated graphite's volume resulting in the formation of porous graphene aggregates. The aggregates were then subjected to ultrasonication for 5 min. at 100 W leading to the formation of exfoliated few-layer graphene.

It was reported that the use of perchloric acid with acetic anhydride increased its oxidation of graphite and thereby ensured intercalation of $HClO_4$ in graphite. Further, in the second step, the microwaves facilitated the decomposition of intercalated graphite due to a rapid increase in temperature. Thus, the use of microwaves in combination with sonication led to 100% exfoliated graphene. It was also reported that the few-layer garphene so produced had an average layer number of less than five and an average surface area of 256.8 μm^2.

In recent years, electrochemical exfoliation of graphite in aqueous solutions of inorganic substances and ionic liquids has gained a lot of significance over the years. Generally, the electrochemical exfoliation of graphite involves cleavage of intercalated graphite in solutions of salts or inorganic precursors undergoing insertion into graphite under electric current. The electrochemical exfoliation offers advantages such as better control of oxidation, intercalation and exfoliation of graphite sheets, hence generating good yields of less defective, high quality graphene [48].

An electrochemical exfoliation process for graphene preparation has been reported by Htwe *et al.* [49]. The method was based on the use of the traditional binary electrode system comprising graphite rod as a working electrode and platinum rod as a counter electrode for electrochemical processes. The two electrodes were immersed in an electrolyte solution containing sulphuric acid and phosphoric acid in one study and in another one, ammonium sulphate in distilled water was used as an electrolyte. A 10 V direct current bias voltage was applied until complete exhaustion of the graphitic anode. After electrochemical exfoliation, graphene is sonicated for about 15 to 60 minutes at ambient temperature and washed with distilled water *via* vacuum filtration. After vacuum drying at 80°C, pure graphene is obtained. In this exfoliation process, the inorganic compounds/ions from electrolyte solution are intercalated between graphite sheets *via* covalent or ionic bonds. Next, the graphite undergoes destruction due to electric potential and graphite sheets separated to form graphene. It was further reported that a comparative study of electrolytes and sonication time showed that the sulphuric acid electrolyte coupled with 45 min. of ultrasonication resulted in the most stable and least defective graphene with a few layers. Overall, from the above examples, it can be inferred that both mechanical and chemical exfoliation methods are cost-efficient and lead to high grade graphene in good yields.

Unzipping/Unrolling of Carbon Nanotubes

The unrolling of single-walled or multi-walled carbon nanotubes (SWCNT or MWCNT) is comparatively a new technique for graphene synthesis. Unzipping of

CNT results in the unfolding of a rolled cylindrical structure into planar graphitic sheets of single or few layers. By and large, a high strain rate of about $10^{8\text{-}10}$/s is the perquisite for breakdown of the C–C bond, leading to unrolling of CNT [50]. Laser irradiation, plasma etching, oxidizing agents, *etc.* are commonly used for the unzipping of SWCNT and MWCNT into mono- and few-layer graphene nanoribbons [51 - 53]. Graphene nanoribbons are basically quasi-monodimensional materials with armchair or zigzag edges [54].

In a recent study, nitrogen doped carbon nanotubes were unzipped to prepare graphene nanoribbons *via* a two-step process [55]. Firstly, an electrochemical process was carried out using 1 M H_2SO_4 solution as electrolyte for a three-electrode arrangement consisting of the nitrogen doped CNT array, platinum mesh, and mercury/mercury (I) sulfate (MMS) as the working, counter, and reference electrode, respectively. A potential of 0.8 V was applied at the working electrode for electrochemical unzipping of N-doped CNT. The unzipped CNTs were then washed thoroughly with deionized water to get rid of impurities. In the next step, the unzipped CNTs were suspended in N-methyl-2-pyrrolidone and subjected to sonication in an ice bath at different powers ranging from 40 W to 200 W (Fig. **3**). Finally, pure graphene nanoribbons were obtained by ultracentrifugation at 40000 rpm to discard the residual N-doped CNTs and other impurities. The method offered an efficient protocol for unzipping of CNTs, leading to graphene nanoribbons of 2 μm length.

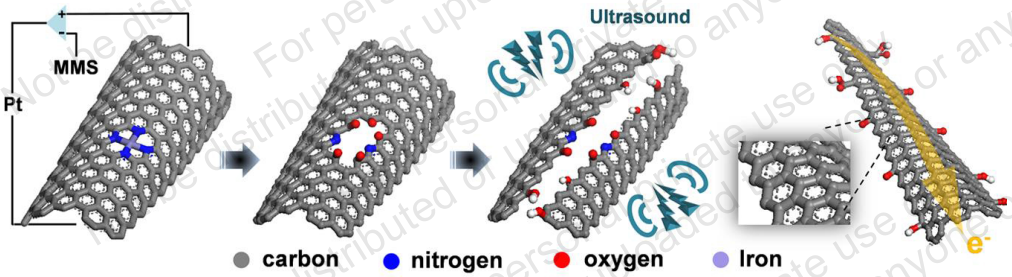

Fig. (3). Two-step synthesis of graphene nanoribbons *via* **(i)** Electrochemical unzipping **(ii)** Ultrasonication. Reprinted with permission from [55]. Copyright © 2019, American Chemical Society.

Plasma etching technique for graphene synthesis has been reported by Jiao *et al*. [56]. In this technique, the MWCNTs were dispersed in 1% aqueous Tween 20 solution and sonicated for 5 min. followed by centrifugation for 10 min. at 16,400*g* to eliminate the aggregates. The MWCNT dispersion was then mounted onto a pretreated Si substrate. Thereafter, the sample was calcined for 10 min. at 350 °C to get rid of the Tween 20. Next, a poly(methyl methacrylate) (PMMA) solution was spin-coated on MWCNTs at 3,000 rounds per minute for 60 s and then scorched at 170 °C on a hot plate for 2 h. This was followed by peeling off

the PMMA-MWCNT film in 1 M KOH solution at 80 °C [57]. Later, the film was cleaned with water and deposited onto a Si substrate by heating at 80 °C for 10 min in an oven. A10 W Ar plasma was employed by the workers to etch the PMMA-MWCNT film by applying a pressure of 40 mTorr. Subsequent to the etching process, the PMMA film was adhered to 3-aminopropyltriethoxysilane (APTES)-treated SiO_2/Si substrate with a preassembled Pt/W marker array. Finally, the PMMA was eliminated by acetone vapour followed by calcination for 10 min. at 300 °C to obtain graphene nanoribbons [57]. The graphene nanoribbons synthesized by this method were obtained with smooth edges and a slender width of 10-20 nm. This process has an advantage that it allows better control over the structure and quality of graphene.

Lately, Li and his research group have demonstrated longitudinal unrolling of carbon nanotubes (Fig. **4**) *via* intercalation of MWCNTs with KNO_3 and H_2SO_4 [58]. The advantage of this method is its scalable and mild protocol for the synthesis of graphene nanoribbons in excellent yields using less amount of H_2SO_4. The typical process involved magnetical stirring of MWCNTs with KNO_3 and H_2SO_4 for 2 h at 300 rpm. Thereafter, $KMnO_4$ was added gradually to the solution followed by stirring for another 2 h at ambient temperature. Then the unrolling reaction was carried out for 2 h in a water bath by slowly raising temperature from 30 °C to 70 °C. After completion of the reaction, the product was purified by sonication and centrifugation to yield pure graphene nanoribbons [59]. It was also revealed that the nanoribbons were single-layer to few-layer graphene with an average height of 2.1 nm and width of 101.8 nm.

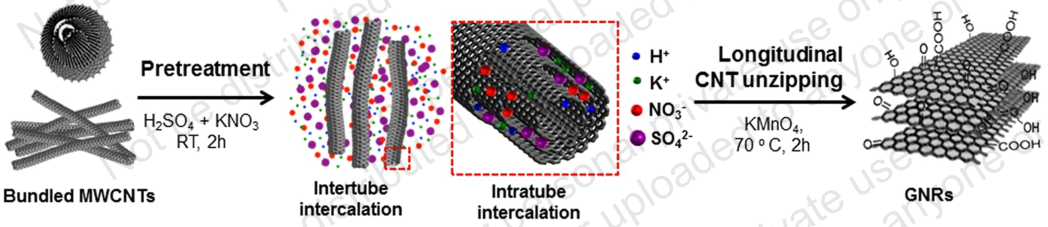

Fig. (4). Graphene nanoribbons are synthesized *via* stepwise longitudinal unzipping of CNTs. Reprinted with permission from [58]. Copyright © 2016, The Author(s).

Electric Arc Discharge

In a characteristic electric arc-discharge method, graphitic rods as a negative cathode and a positive anode are placed at a distance of few millimeters from each other and high current is applied to the electrodes to decompose the graphite rods to generate carbon nanostructures which pile up over the cathode or around the chamber walls [60]. The electric arc method for graphene synthesis has been investigated by several researchers. The advantage of electric arc method is that it results in the production of highly crystalline and pure graphene [61]. Recently a

gram scale synthesis of graphene has been established by Wu *et al*. [62]. The method was based on alternating current arc discharge method. An AC arc-discharge was performed in a water-cooled stainless steel chamber containing a mixture of nitrogen and hydrogen as buffer gas. Two graphite electrodes at a distance of 1 mm were used in the chamber. An AC of 150 A was applied at 400 Torr pressure. The electric discharge led to the consumption of two graphite electrodes in a short time of 4 min to 5 min and the carbon products were deposited on the inner and top wall of the chamber. The products were collected and annealed in air for an hour at 400 °C to obtain pure few-layer graphene. The method presented several advantages such as short reaction time, production of gram quantities of graphene and generation of high quality graphene sheets.

In another method, graphene and N-doped graphene were prepared *via* arc discharge by utilizing anodic carbon fillers *viz*. graphite, graphene oxide (GO) and polyaniline (PANi) [63]. In this method, an arc discharge apparatus was employed with graphite cathode and hollowed graphite anode positioned horizontally. Graphite powder, GO and PANi were homogeneously mixed and used as anodic carbon filler. For preparation of N-doped graphene, the arc chamber was first maintained at a pressure of 5×10^{-2} Torr, then filled with He, H_2, and NH_3 gases. The chamber pressure was then sustained at 550 Torr. For graphene, He and H_2 gases were used. A voltage of 30 V and current of 150 A were applied. The discharge resulted in the collection of graphene and N-doped graphene materials at the upper part of chamber. The graphene and N-doped graphene flakes produced by this method exhibited high crystallinity and large number of active edges that displayed super-capacitance.

Laser Ablation

Pulsed laser ablation or pulsed laser deposition is a reductive technique consisting of the production of micro or nanosized materials *via* removal of small portions of bulk substrates using a focused pulsed laser beam. In a typical laser ablation method, a pulsed beam is focused on graphite containing catalytic material in the presence of inert gas and high temperature resulting in ablation of carbon particles [64].

The main advantage of laser ablation techniques is that it yields highly porous graphene materials. A femtosecond laser ablation process for synthesis of extremely porous graphene has been demonstrated by Russo and co-workers [65]. In this approach, a highly oriented pyrolytic graphite (HOPG) was used as a target, placed at the bottom of a quartz cell filled with water and ablated by a femtosecond laser with a pulse duration of 35 fs. The HOPG was ablated continuously for 20 min. to produce highly porous graphene floating in the air-

water interface. It was further revealed that a six-layered spongy graphene with an irregular 3D porous structure with an average pore size of 15-20 nm was generated by this method.

A mechanism for graphene synthesis was also proposed by researchers. According to them, the laser beam simultaneously initiates decomposition of water, generates reactive molecules O_2, H_2, and H_2O_2 and exfoliates graphite, causing un-stacking of graphite sheets. Later, oxidation of graphene sheets takes place due to O_2 and H_2O_2 species producing several layered graphene oxide (GO) with sp^3 hybridized carbon atoms due to oxygen bonded atoms. Then, similar to the coal gasification mechanism, the sp^3 carbon atoms of the GO react with oxidized species. Subsequently, the formation of CO and CO_2 molecules occurs, leaving behind carbon vacancies and creating pores of nanodimension. This finally results in the production of porous graphene which floats at the water-air interface from where it is readily collected. Thus, this method affords large-scale synthesis of graphene in a short time and with high porosity.

Very recently, a novel single step liquid phase laser ablation technique has been used by Juvaid and his research group to produce a bilayer graphene [66]. In this method, a commercially graphite bar was suspended in deionized water (ablation medium) and ablated with a KrF excimer laser beam of 248 nm wavelength. The laser irradiation generated plasma which caused exfoliation of graphene films in water. Then, after half an hour of laser exfoliation, the Si/SiO_2 substrate was immersed in deionized water to collect the graphene films and later subjected to a natural drying process. Consequently, this cost-effective method produced bilayer graphene films with a high crystalline nature. Thus, it can be inferred that the laser beams produce high thermal energy which helps in overcoming the van der Waal bonds between the hexagonal sheets of graphite and leads to the formation of graphene.

Oxidative Exfoliation-Reduction of Graphene Oxide

Graphene oxide (GO) is generally prepared by oxidation of graphite using oxidants like $KClO_3$, $KMnO_4$, *etc.* in acidic media (HCl, H_2SO_4 and HNO_3, *etc.*). The first ever synthesis of graphene oxide *via* intercalation of graphite flakes was reported by Schafhacutl in 1840. Since then, various methods have been employed to synthesize graphene oxide including the Brodie's method [2], Staudenmaier method [67], Hofmann method [19, 68], Hummers method [69] and also other modified and improved methods [70, 71]. The reduction of graphene oxide leads to the production of graphene or reduced graphene oxide. In the following sections, oxidation and reduction methods have been briefly discussed.

Graphene Oxide Synthesis

Diverse methods used for oxidation of graphite to form graphene oxide (Fig. **5**) are as follows:

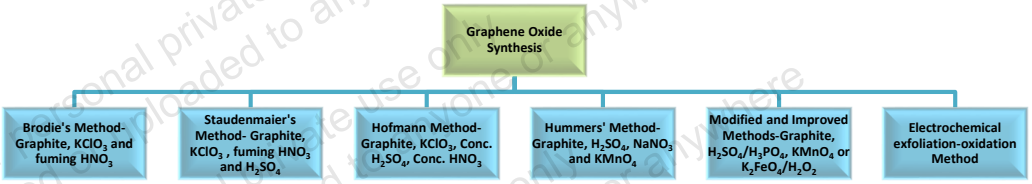

Fig. (5). Diverse methods for synthesis of graphene oxide.

a) Brodie's Method- Graphene oxide was fabricated by Brodie in 1859 using potassium chlorate and fuming nitric acid as oxidants. The synthesized product was a mixture of graphene and graphene oxide and soluble in water. The composition of the product as determined by elemental analysis was found to be 61.04% C, 1.85% H, 37.11% O. The shortcomings of this method were lengthy reaction time and evolution of hazardous gases.

b) Staudenmaier's Method- Staudenmaier's method (1898) was an upgrade to Brodie's method. This method used sulphuric acid in addition to fuming nitric acid and multiple aliquots of potassium chlorate solution, thereby escalating the acidity of the reaction mixture. This led to production of an extensively oxidized graphene oxide. However, this process was also time consuming and released toxic gases, hence it was not so suitable.

c) Hofmann's Method- In 1937, Hofmann and his research group demonstrated the use of concentrated nitric acid along with concentrated H_2SO_4 and $KClO_3$ to prepare graphene oxide.

d) Hummmers' Method- Hummers and Offeman in 1958 elucidated a novel method for the oxidation of graphite. The process was based on stirring of graphite powder with a combination of concentrated H_2SO_4, $NaNO_3$ and $KMnO_4$. When the stirring was complete, the reaction mixture was diluted with water and hydrogen peroxide and filtered. The product was then washed and dried to obtain pure graphene oxide. Although the method yielded highly oxidized graphene oxide in good yields, its major flaws were the explosive reaction process and the evolution of poisonous NO_2 and N_2O_4 gases.

e) Modified and Improved Methods- Over the past few years, improved and modified methods have been developed to conquer the drawbacks of the above mentioned routes and enhance the product yield. In 2010, Marcano and his co-

workers designed an improved method for GO synthesis [72]. In this method, they substituted sodium nitrate with a 9:1 mixture of H_2SO_4/H_3PO_4 and raised the concentration of $KMnO_4$. The highlight of this method was that a greater yield of hydrophilic graphene oxide was produced without the release of toxic nitrogenous gases. Recently, an improved Hummers method was demonstrated by Chen *et al.* [73] for GO synthesis using $KMnO_4$ and concentrated sulfuric acid. The advantage of this method was that $NaNO_3$ was not used, which prevented the evolution of hazardous gases Further, very recently an improved $NaNO_3$-free Hummers method was devised by Yu *et al.* employing $KMnO_4$, K_2FeO_4 and concentrated H_2SO_4 as oxidants and boric acid as a stabilizing agent [74]. This protocol was extremely efficacious and environmentally-friendly.

Another non-explosive improved method for GO synthesis was demonstrated by Ranjan *et al.* [75]. The method was a modification of Marcano's method. In this method, graphite flakes and $KMnO_4$ (taken in 1:6 ratio) were mixed using mortar and pestle for 5 min. and kept at 5 °C (the pre-cooling protocol). Next, a solution of sulphuric acid and phosphoric acid (taken in the ratio 9:1) was prepared separately and again pre-cooled at 5 °C. Both the solutions were mixed. At this step, no explosive reaction occurred and temperature also remained constant at room temperature. The suspension was then heated at 65 °C and was continuously stirred for 24 h. Later, the brown colored suspension was cooled down by adding 400 ml of deionized ice water. Then, H_2O_2 (7 mL) was added and stirred to obtain a golden yellow solution indicating the formation of graphene oxide. To the solution, distilled water was added and the precipitate was allowed to settle down. The precipitate was then washed with deionized water, HCl and ethanol, centrifuged and the suspension was decanted to obtain a gel-like substance. Finally, the gel was degassed for 24 h in a desiccator to obtain GO. Thus, the modified approach was cost-effective, free from toxic gas emission as well as non-explosive in nature, generating high purity GO.

Similarly, a modified Hummers approach using a mixture of sulfuric acid, phosphoric acid and nitric acid as intercalating sources and potassium permanganate and hydrogen peroxide as oxidants has been investigated by Al-Gaashani and co-workers [76]. This chemical oxidation method was free from poisonous gas expulsion, a low temperature process and reliable producing high quality of graphene.

f) Electrochemical Exfoliation-Oxidation Method- In a characteristic electrochemical exfoliation-oxidation method, two electrode system with graphite electrode as working or anodic electrode is used with an oxidizing electrolyte [77]. The basic approach is exfoliation of graphite by intercalation followed by oxidation to produce GO.

Of late, a high yielding electrochemical exfoliation procedure for GO preparation has been reported by Wang and his research group [78]. A two electrode system with graphite foil as a working electrode and Pt foil as a counter electrode placed at a distance of 3.0 cm was set-up. A low voltage of 4.0 V from a DC power source was applied and a mixture of H_2SO_4 (1 mol L^{-1}) and $KMnO_4$ (0.4 g) was used as electrolyte. The exfoliation was carried out for an hour. Thereafter, the electrolyte (retreated by sonication at 200 W of power for 30 min.) caused oxidation of the exfoliated graphene. The process continued for 10 hours. The GO was purified by washing with deionized water to remove the electrolyte ions and collected by vacuum filtration using a 0.22 mm microfiltration membrane. Finally, pure GO was obtained by drying at 60 °C for about 12 h. In this process, H_2SO_4 caused intercalation and exfoliation of graphite to afford graphene while $KMnO_4$ resulted in the oxidation of graphene to form hydrophilic graphene oxide. This method generated a 90% yield of GO.

A similar electrochemical oxidation process to produce graphene oxide was reported by Pei *et al*. using graphite intercalation compound paper as anode and Pt as cathode with a 5 V DC power supply, and diluted H_2SO_4 solution as an electrolyte [79]. Overall, the method presented a benign and efficient protocol for GO synthesis (Fig. **6**).

Graphene Oxide Reduction

The reduction of graphene oxide to reduced graphene oxide (rGO) or graphene can be accomplished by diverse methods such as chemical reduction, thermal annealing, photo or microwave reduction methods, electrochemical and solvothermal reduction (Fig. **7**). The reduction process removes oxygen functionalities from GO and re-establishes the aromatic framework of graphene.

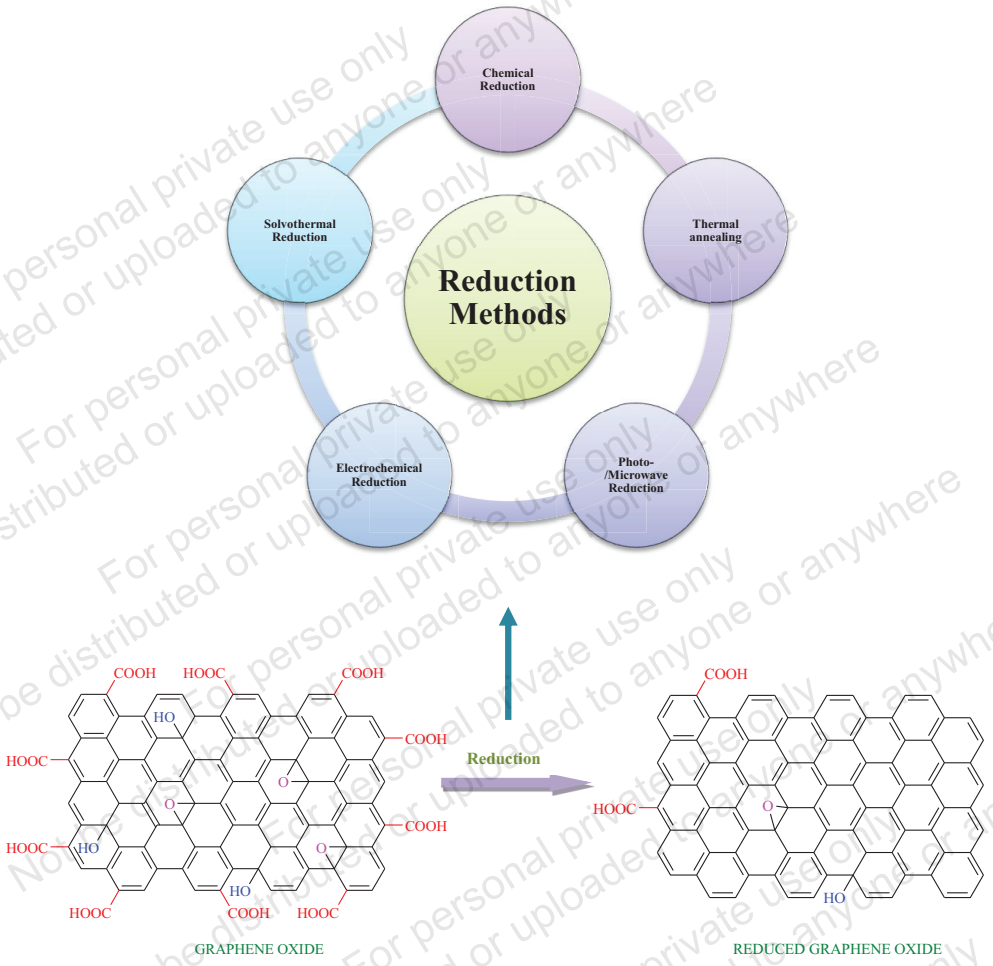

Fig. (7). Reduction of graphene oxide by diverse methods.

a) Chemical Reduction- The most commonly used method for reduction of graphene oxide is chemical reduction. The reduction of GO is basically carried out using chemical reductants in water. A variety of reducing agents such as hydrazine [80], lithium triethylborohydride [81] and elemental sulphur [82], L-ascorbic acid [83], glycine [84], starch [85], vanomycin [86], polydopamine [87], algal extracts [88], bacterium [89], artemisinin [90], green tea extract [91], *Aloe vera* [92], *etc.* have been used to prepare rGO from GO. Despite the scalability of this method, chemical reduction of GO suffers a setback because the rGO so obtained exhibits reasonably poor surface area and electronic conductivity [93].

b) Thermal Annealing- Annealing is a process which is usually carried out in vacuum [94], air [95], in inert [96] or reducing environment [97]. The rapid heating of GO at elevated temperature, not only exfoliates it but also removes oxygen functionality. Further, the thermal annealing introduces morphological defects and damages the graphene sheets due to the release of carbon dioxide [98] which enhances the electronic properties of the reduced form. Additionally, it has been proven that the more elevated the annealing temperature, the better is the reduction and the greater is the surface area of rGO [99].

c) Microwave and Photo-Reduction- The microwave reduction method is quite advantageous because using this method one can simultaneously carry out reduction as well as doping of GO along with fabrication of hybrid composites in short reaction time [100 - 102]. In an instance, it was reported that microwave reduction of graphene oxide powders produced rGO within just 3 minutes [103]. Recently, photo reduction of GO has also emerged as a neat and straightforward technique using solar light [104], ultraviolet light [105], and visible irradiation [106]. These methods lead to supreme quality rGO. Besides, by employing laser beam, the reduction is accomplished in femto-seconds [107].

d) Electrochemical Reduction- The prime highlight of this method is that GO reduction of GO can be achieved in aqueous buffer solution at ambient temperature without using hazardous chemical agents. In this method, the reduction process is performed in an electrochemical cell and reduction of GO occurs *via* the exchange of electrons between the electrodes and GO [108 - 110]. This method produces rGO with a high carbon to oxygen ratio and excellent electrical properties. However, the only concern is scalability that needs to be improved [111].

e) Solvothermal Reduction- In this approach, GO is dispersed in a solvent and reduction is carried out under supercritical conditions which arise due to heating in a sealed vessel [112, 113]. Moreover, solvothermal reduction aided by ultrasonication leads to rapid formation of rGO [114]. Supercritical water is a commonly used green solvent in this technique and results in elimination of functionalities in GO thereby restoring its aromatic framework [115]. The solvothermal route using water as solvent is also branded as hydrothermal reduction [116, 117].

In addition to the above methods, multi-step reductions are also well known for reduction of GO [118, 119]. The multi-step reduction is an extremely capable process which is known to generate high quality rGO. This method is nothing but an amalgamation of the above-mentioned methods.

BOTTOM-UP SYNTHESIS

The bottom-up approach deals with assembly of graphene from carbon precursors, *i.e*. step by step, building up graphene from carbon particles [120]. Chemical vapour deposition (CVD), epitaxial growth, template synthesis, pyrolysis, substrate free synthesis, and total organic synthesis are commonly used bottom-up strategies.

Chemical Vapour Deposition

Chemical vapour deposition (CVD) technique involves decomposition of volatile precursors on a substrate at elevated temperature in the presence of vacuum to prepare nanomaterials [121]. It is an extensively used method for industrial scale preparation of graphene. In this method, carbonaceous precursors undergo pyrolytic decomposition on crystalline substrate resulting in the creation of adsorption sites on the substrate's surface and thereby promoting the growth of high quality homogeneous thin films of graphene [122]. Generally, metals are used as substrates as well as catalysts, whereas carbonaceous precursors include hydrocarbons or biomass materials [123 - 125]. Recently, silicon carbide [126], boron nitride [127], quartz [128], silica [129], *etc.* have also been used as substrates for CVD. The greatest advantage of using CVD is that it produces high quality graphene with less defects, exceedingly cross-linked structure and higher surface area [130]. However, the method also suffers from some shortcomings like high production cost and, need for purification to remove catalysts which can be overcome by optimizing the process to low temperature and pressure [131].

Singh and his research group in their recent work have investigated nickel-catalyzed thermal chemical vapour decomposition of acetylene on steel (GCr15) for graphene synthesis [132]. The method typically involved the use of GCr15 alloy steel discs of 24 mm diameter. The discs were mechanically ground and immersed in acetone and isopropanol, respectively, followed by sonication. Thereafter, the surfaces of steel discs were electroplated with a nickel layer of 25 μm thickness to assist graphene deposition. Acetylene was used as a carbon source with hydrogen gas as a reducing medium. The discs were mounted in a ceramic boat and kept inside the quartz in the centre of the furnace. Then, a vacuum of 1.2×10-2 Torr was created inside the furnace and maintained. Next, the discs were heated at room temperature and at various growth temperatures ranging from 650 °C to 950 °C in 30 min. followed by annealation for 40 min under H_2 gas flow (20 sccm) at the growth temperature. Then, acetylene (6 sccm) was made to flow through the sample for 20 min. along with H_2 (20 sccm). At elevated temperature, the decomposed carbon atoms were absorbed by the nickel and acetylene flow was stopped after reaction completion. Then the cooling

process in a hydrogen-rich environment resulted in the formation of graphene due to carbon precipitation. Further, acetylene flow rates (6, 8, and, 10 sccm, growth temperature (850 °C and 950 °C) and reaction time (10 and 20 min.) were also optimized to afford the highest quality graphene. Overall, the study showed that the highest quality graphene over nickel was obtained at a growth temperature of 850 °C for a reaction time of 10 min. under 6 sccm acetylene gas flow rate. This is because at 850 °C, the graphene formed exhibits higher graphitization, and in a short reaction time, the number of graphene layers formed is less and at reduced flow of acetylene, graphene with low defects is formed [133].

In another study, graphene was prepared using a plasma enhanced CVD method. Munoz *et al.* for the first time have demonstrated growth of graphene on silicon dioxide *via* plasma CVD at a low temperature [134]. In this approach, the ASTEX AX 4500 ECR system was used as a microwave power source, a two zone chamber and a two-stage pumping system were also employed. Acetylene and hydrogen gas mixtures and silicon wafers (111) with native oxide as substrate were used in this process. The method involved two steps-(i) growth of high quality graphitic seeds with controlled treatment and density and (ii) promotion of edge growth leading to graphene film formation. In this method, hydrogen flow was adjusted at 50 sccm while acetylene flow was tuned in the range from 0.9 to 0.34 sccm for nucleation and from 0.8 to 0.24 sccm for growth of graphene films. Plasma was generated by applying a power of 200 W and a temperature ranging from 550^{o}C to 650^{o}C was set-up to carry out CVD. After completion of nucleation and growth steps, annealing of graphene films at 650^{o}C was performed in vacuum for 2 h to produce supreme quality graphene films. This method resulted in the fabrication of a monolayer and a few layer graphene films with domain sizes ranging from 50 nm to >300 nm. Additionally, this strategy offered advantages including low temperature process, avoidance of film transfer and scalability.

Epitaxial Growth

The term epitaxial has been derived from two Greek words, “epi” (meaning above) and “taxis” (meaning arrangement), respectively [135]. In epitaxial growth technique, a crystalline film grows over a single crystalline substrate. There are usually two kinds of growth *viz*. homo-epitaxial (when film and substrate are of the same material) and hetero-epitaxial (when film and substrate are of different materials) [136]. For graphene synthesis, a mono crystal of silicon carbide is used as a substrate for epitaxial growth. This technique is usually performed at elevated temperatures under ultra-high vacuum (UHV) [137]. At high temperatures, silicon sublimes, leaving behind carbon atoms which undergo sp^2 hybridization and arrange to form aromatic hexagonal ring network, stimulating graphitization leading to the formation of graphene [138]. This method offers commercial

synthesis of graphene but it has certain drawbacks which include expensive protocols and production of graphene lacking uniformity [139]. However, in recent years, modified epitaxial growth methods have been developed to overcome these issues. Of late, Lalmi and his research group have demonstrated a large scale trilayer graphene synthesis *via* epitaxial growth on 6H-SiC (0001) [140]. The typical process included hydrogen etching of SiC at 1550°C to produce 6H-SiC (0001). Thereafter, 6H-SiC (0001) was heated at 1000°C in a semi-ultra high vacuum chamber and later heated at 1550°C in an atmosphere of argon, causing graphitization. An active graphene layer attached to the substrate was obtained and later cooled down for further processing. The method yielded flower-shaped and wrinkled three-layered graphene (Fig. **8**). The unique morphology of graphene is ascribed to partial dislocations between ABA and ABC stacking in trilayered graphene.

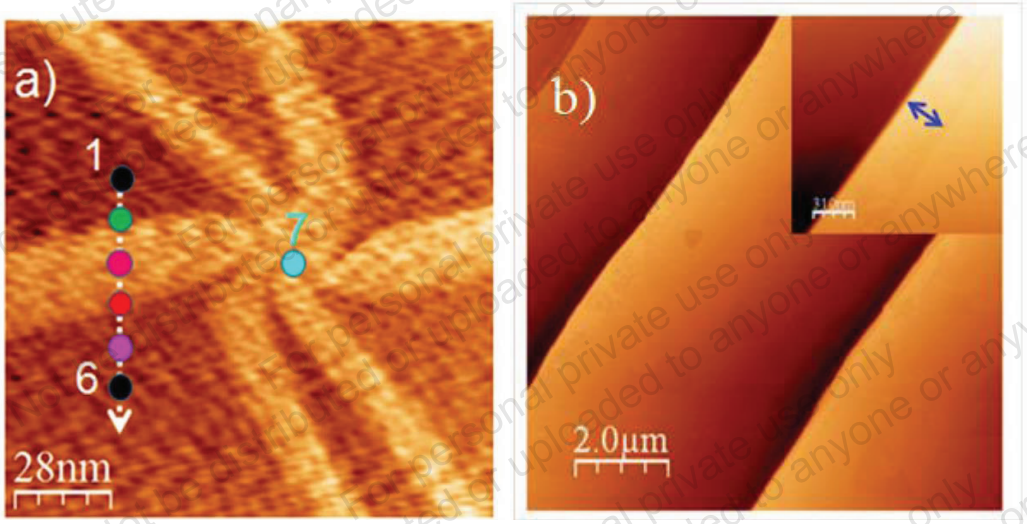

Fig. (8). STM images showing **(a)** flower-shaped domain of graphene **(b)** three-layered graphene. Reprinted with permission from [140] Copyright 2014, The Author(s).

In recent years, other than silicon carbide, boron nitride, metals like copper, nickel, *etc.* have also been used as substrates for epitaxial growth of graphene. For instance, Xu *et al.* reported epitaxial synthesis of graphene on commercially available Cu foil [141]. The method involved placing Cu foil on a quartz substrate and mounting it on a CVD furnace and annealing at 1030°C under the flow of Ar (500 sccm) to yield a Cu (111) crystal. The single Cu crystal (111) was then constantly moved past the furnace at a speed of 2.5 cm min^{-1}. For graphene growth, the CVD furnace was heated to 1030°C under the flow of Ar at 500 sccm and H_2 at 10 sccm. Then methane is made to flow at 1-5 sccm through the CVD

reactor. Graphitization leading to growth of graphene film was observed and upon completion of growth, the system was allowed to cool under the atmosphere of Ar (500 sccm) and H_2 (10 sccm). The method afforded ultra high quality graphene film in just 20 min. by epitaxial growth of graphene islands over a single crystal of Cu (111). These islands combine on the Cu surface to form a graphene film displaying exceptional crystallinity. On the whole, the technique presented a rapid and high yielding protocol for ultra-crystalline graphene film synthesis.

Template Synthesis

In template synthesis, an organic or inorganic material is employed as a template to express the growth of novel materials [142]. For graphene fabrication, carbon precursors are used along with pre-synthesized templates. This method is known as a hard-template synthesis. In hard template synthesis, a template works as a mold for replication of carbon materials, and no considerable chemical interactions occur between the template and the carbon precursor [143]. There is another approach in which molecular self-assembly of templates takes place *via* hydrogen bonding, hydrophobic/hydrophilic interactions, ion pairing, or dative bonding. This type of template synthesis involves chemical interactions between templates and carbon and is known as soft-template synthesis [144]. The synthesis of graphene *via* template synthesis using metal oxides [145], micelles [146], polymers [147], *etc.* has been reported to produce graphene with a well ordered structure and high quality.

Yang and co-workers have reported a simple soft-hard template method for the synthesis of graphene [148]. In this method, cetyltrimethyl ammonium bromide (CTAB) was employed as a soft template, silica (SiO_2) obtained from tetramethoxysilane (TMOS) was used as a hard template, and pyrene as a source of carbon (Fig. **9**). The process began with hydrolysis of TMOS in water under acidic conditions at pH=3 at ambient temperature of 2 h. Then, CTAB solution and pyrene were added to it and the reaction mixture was stirred for a few minutes. The homogenous sol so obtained was spin coated on quartz and silicon substrates. Subsequently, the films were thermally treated to vapourize the solvent and to further induce solidification of the composite. Later, the SiO_2/CTAB/pyrene composite was ground and annealed at 900°C for 2 h under N_2 atmosphere to obtain graphene loaded on silica substrate (SiO_2/graphene/SiO_2 composite). The silica was removed by treatment of the composite with HF (10% aqueous solution) for 48 h to obtain pure graphene. The graphene films obtained by template self assembly synthesis were of high quality and had thickness of the order of 1 nm and a size of about 5 μm.

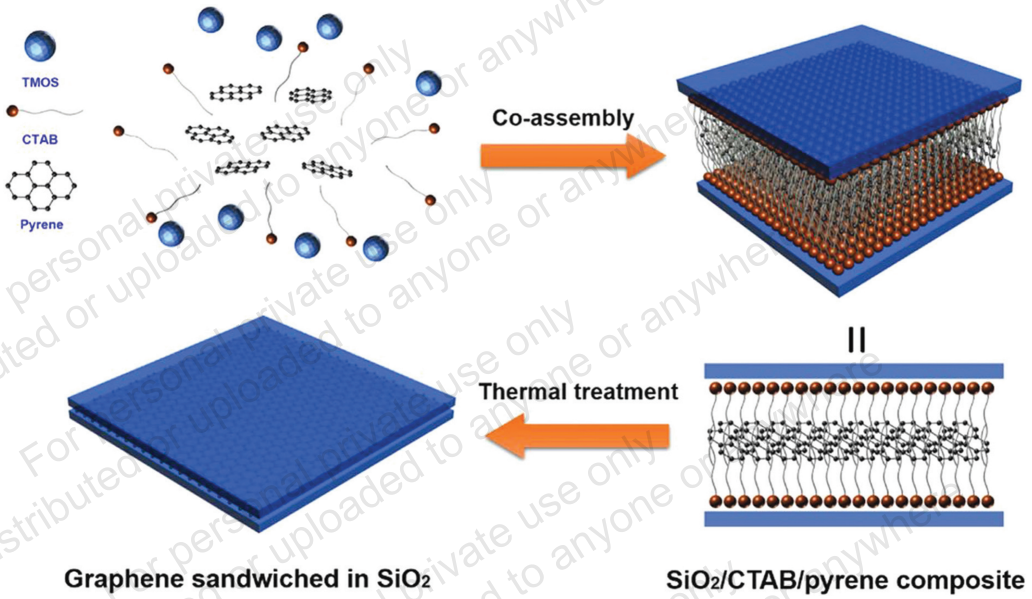

Fig. (9). Template synthesis of graphene film. Reprinted with permission from [148]. Copyright 2014, The Author(s).

In another method, micelle template based synthesis was used to fabricate N-doped mesoporous graphene [149]. Huang *et al.* first mixed 50 mL of GO suspension and 150 mL of hydrazine hydrate solution at ambient temperature *via* vigorous stirring for 12 h. Afterwards, 20 mL of F127 micellar solution was added to the above suspension and the reaction mixture was stirred for 2 h. Later, HCl (14 mL) was added and the mixture was briskly stirred for 24 h. The precipitate was collected by vacuum filtration and sintered at 350ºC for 5 h in argon atmosphere and for another 5 h at 900ºC to generate highly mesoporous graphene. In order to obtain N-doped graphene, 50 mg of graphene and 250 mg of cyanamide were mixed for 15 min. followed by sintering at 800ºC for 3 h in argon atmosphere. Thus, this method was quite efficient and afforded graphene with homogenously distributed mesopores, a large pore volume and a huge surface area.

Pyrolysis

Pyrolysis is a high temperature treatment involving thermal decomposition of a carbon source leading to the formation of C atoms that rearrange to form a graphitic carbon framework, leading to the formation of graphene. The method is inexpensive and produces graphene with superb purity but with few defects [150]. A gram scale synthesis of multi layer graphene was fabricated by Hong *et al.* [151]. This method involved pyrolysis of poly(methyl methacrylate) (PMMA) on

nickel microparticles in the restricted microzones created by organophilic montmorillonite (OMT). The typical process involved a pyrolysis apparatus with a quartz tube. The PMMA sample was placed in a quartz tube and placed inside a furnace fitted with a thermocouple under N_2 atmosphere. The carbonization was carried out at 1000°C for 8 min. and the product was obtained as black powder by cooling the reactor under N_2 flow. The product was further purified by etching the impure graphene powder with HF (10 wt.%) and HNO_3 (30 wt.%) under ultrasonication at ambient temperature followed by filtration, washing and drying at 80°C. Initially, PMMA sample was obtained by mixing methyl methacrylate, OMT and benzoyl peroxide under magnetic stirring followed by heating at 85°C under N_2 atmosphere. A thick paste was formed to which Ni particles were added and polymerization was carried out for 48 h at 60°C. Thus, wrinkled graphene sheets with a thickness of 1-4 nm and with few defects were achieved by this method. It was further reported that the addition of OMT restricts the pyrolytic carbon derivatives obtained by PMMA decomposition in microzones and improves yields of graphene produced catalytically by Ni particles in the microzones. Thus, the method offers inexpensive and scalable production of graphene.

Recently, the spray pyrolysis method has been used for the synthesis of graphene. In spray pyrolysis, a precursor solution is sprayed on a heated surface to produce aerosol droplets which undergo reaction and decompose to form particles and thin film [152]. Zou and his research group have demonstrated production of graphene nanosheets by spray pyrolysis of precursor's *viz*. iron carbonyl and pyridine [153]. In this process, the precursors (carbonyl and pyridine) were introduced into a quartz reactor at 5 mL min^{-1} flow rate. Also, N_2 was made to flow through the reactor at 600 L h^{-1}. The resultant sample was collected and mixed with excess ammonium chloride followed by heat treatment at 800°C for 30 min. in a quartz tube to remove the residual precursors. Finally, pure graphene nanosheets of good quality were obtained by washing, filtration and drying.

Substrate Free Synthesis

Substrate free synthesis is a comparatively newly developed strategy where graphene is synthesized *via* gas phase reactions in the absence of substrates, solvents and catalysts. In general, this method includes four strategies including carbonization, arc discharge, combustion, and atmospheric plasma [154]. The advantages of this method comprise scalability and production of high quality graphene with a tunable number of layers, low content of oxygen, and enhanced purity [154].

A substrate free, argon-plasma induced synthesis of graphene sheets was reported by Dato and his research group [155]. The researchers carried out the graphene synthesis in an atmospheric pressure microwave plasma reactor (Fig. **10a**) equipped with a quartz tube for conduction of argon gas stream (1.71 L/min.) *via* a microwave guide. This stream generates argon plasma. Further, with the aid of an alumina tube placed concentrically within the quartz tube, aerosols comprising argon gas (2 L/min.) and ethanol droplets (4×10^{-4} L/min.) were injected straightforwardly into the argon plasma. The ethanol droplets resided within the plasma for a very short time (10^{-1} s) during which these droplets evapourated and dissociated within the plasma forming a solid carbon material. Subsequently, the reaction product *i.e.* graphene after moving through the plasma was quickly cooled and collected on nylon filter membranes. It was reported that the rate of graphene sheets collected on filters was 2 mg/ min, for an input of carbon present in the ethanol of 164 mg/ min. Further, the graphene sheets collected on the filters were dispersed in methanol (Fig. **10b**) and sonicated for 5 min. to obtain a black homogenous suspension. The graphene sheets are composed of mono- and bi-layers as characterized by transmission electron microscopy (Fig. **10c**). The highlight of this method was continuous production of atomically thin graphene sheets.

In another instance, a multi-layer graphene sheet with a large specific surface area was produced by employing substrate free gas phase synthesis. Liu and Zhang have demonstrated a substrate free fabrication of graphene in a CVD reactor comprising quartz tube placed inside a horizontal furnace [156]. In the first step, camphor was put inside the tube and argon gas flowed through it at atmospheric pressure. The camphor sublimed on heating at 180°C and the volatilized camphor was pyrolyzed at 800-850°C in the furnace. The reaction was accomplished in 40 min., producing a graphene film which adhered to the wall of the chamber. The film was later scraped off and collected in the quartz tube. A graphene film of a large surface area of about 1 cm×1 cm was obtained by this method. Other advantages of this method include scalability and inexpensive production of graphene.

Total Organic Synthesis

The synthesis of graphene from polycyclic aromatic hydrocarbons (PAHs) constitutes total organic synthesis of graphene. PAHs are defined as 2D graphene fragments composed of all sp^2 hybridized carbons and can be readily modified by using appropriate aliphatic chains to tune the solubility of the product [157, 158]. In this method, suitable PAHs are chosen and used to prepare good quality graphene at high yields *via* a facile reaction pathway. Several reactions such as Suzuki coupling, Yamamoto coupling, Diels-Alder's cylcoaddition, *etc.* have been employed for synthesis of nano-graphene materials [159]. Recently, Vo and his research group have demonstrated a total organic synthesis of N-doped graphene nano ribbons [160]. The process involved several steps. In the first step, phenanthrene-9,10-dione was mixed with 98% sulfuric acid and N-bromosuccinimide was added to the mixture. The reaction mixture was then stirred vigorously at ambient temperature for 8 h. Then, ice-cold water was added to the reaction mixture and filtered to obtain orange colored 2,7-dibromophenanthrene-9,10-dione. In the next step, 5,10-dibromo-1,3-diphe-yl-2H-cyclopenta[l]phenanthren-2-one was synthesized by addition of 2,7-dibromophenanthrene-9,10-dione and 1,3-diphenylacetone methanol under stirring. Then, the reaction mixture was refluxed for 2h after addition of 0.3 M KOH solution drop-wise to the reaction mixture. After filtration, a green colored product was obtained. Next, 5-(phenylethynyl)pyrimidine was prepared by reaction between triethylamine, toluene, 5-bromopyrimidine, and triphenylphosphine in the presence of copper iodide. After degassing the suspension for 15 min., bis(triphenylphosphine)palladium (II) chloride was added. The reaction mixture was again constantly degassed for 15 min. followed by heating at 60 °C and stirring for 30 min. Later, phenylacetylene was added to the reaction mixture and heated at 65-70 °C for 18 h. After filtration and column chromatography, the product was isolated.

In the next step, a reaction between 5,10- dibromo-1,3-diphenyl-2H-cyclopenta[l]phenanthren-2-one, 5-(phenylethynyl)pyrimidine and diphenyl ether was carried out by refluxing for 24 h. this led to formation of 5-(6,11-dibromo-1,-,4-triphenyltriphenylen-2-yl)pyrimidine. Subsequently, bis(cyclooctadiene)nickel was added to a mixture of 2,2'-bipyridyl and 1,5-cyclooctandiene in dried N,N-Dimethylformamide as solvent and heated at 60 °C for 30 min. The degassed solution of 5-(6,11-dibromo-1,3,4-triphenyltriphenylen-2-yl)pyrimidine in toluene was added to the reaction mixture. The reaction mixture was then heated to 80 °C for 3 days and then cooled followed by the addition of methanol/water mixture (50mL/10mL). Thereafter, the slurry was filtered, washed with methanol, concentrated HCl, sodium hydroxide/methanol solution, water, and hexane, followed by drying. Finally, a polymer product was obtained. In the last step, the polymer and dichloromethane were sonicated. Then, iron (III) chloride dissolved in nitromethane was added to the above suspension. Next, nitrogen gas was passed through the reaction mixture for 15- 24 h under stirring condition. Then ethanol was added and the reaction mixture was filtered. The reaction product was then washed with concentrated HCl, water, and methanol/sodium hydroxide solution to obtain a black solid. This solid was dried at 50 °C for 24 h to yield a black powder of N-doped graphene nanoribbons. Thus, this method produces large quantities of high quality N-doped graphene *via* a strategy based on Yamamoto coupling of N-doped precursors and cyclodehydrogenation through Scholl reaction.

A similar scheme was reported by Dichtel *et al.* who used poly(phenylene ethynylene) to produce graphene nanoribbons [161]. The process was based on Asao-Yamamoto alkyne benzannulation [162] promoted by Cu(II) and Brønsted acid that proceeds *via* a benzopyrylium intermediate to generate precursors for nanographene which are further oxidized by Scholl reaction to produce nano graphene ribbons. In this process, diynes undergo benzannulation to form a polyaromatic hydrocarbon intermediate which undergoes oxidation to form nanographene derivatives. The process was quite efficient and resulted in the production of good quality graphene nanoribbons.

Biosynthesis of Graphene and its Derivatives

Besides the aforementioned methods, biosynthesis has also emerged as a sustainable strategy for of preparation of graphene and its derivatives. The biomolecules derived from living organisms or cells or plant extracts serve as reducing, capping as well as stabilizing agents for the synthesis of graphene materials thereby eliminating the use of hazardous chemical agents [163]. Recently, Khanam and Hasan have reported a benign biosynthesis of graphene using extracts of *Allium cepa* (onion) as non-toxic reducing agents [164]. In this

method GO was synthesized by modified Hummers method and then reduced by extracts of *Allium cepa* to produce graphene. The onion skins were first peeled off; the scales were chopped up and then blended to produce juice. Then, about 10 mL of the onion juice was added to GO and the suspension was sonicated for 30 min. Thereafter, the suspension of GO in juice was stirred for 6 h at ambient temperature and the color of dispersion changed from brown to black. This confirmed the transformation of GO to graphene. The mixture was then filtered and the impure graphene was washed with ethanol and water followed by drying to yield pure graphene. Thus, this method afforded a green route for efficacious and economically compatible production of graphene. It was further reported that the graphene so obtained was thin, crumpled and multilayer with a thickness of the order of 140 nm. In another report, green tea leaf extracts containing polyphenols which can serve as reducing and stabilizing agents were used for biofabrication of reduced graphene oxide.

The microbial reduction of graphene oxide is also an important biological method for production of rGO or graphene. For instance, Gurunathan and co-workers have reported reduction of GO using *Escherichia coli* biomass [165]. The *E. coli* bacteria were grown on LB medium (Luria-Bertani broth comprising 10 g tryptone, 5 g yeast extract, and 10 g/L NaCl) in an Erlenmeyer flask. The flask was incubated in a rotatory shaker agitating at a speed of 120 rpm/min for 21 h at 37^{o}C. The bacterial culture after incubation was centrifuged at 10,000 rpm/min. then, the bacterial biomass was employed for reduction of GO. Next, to a GO dispersion, about 200 mg of *E. coli* biomass was added and the mixture was stirred for 72 h at 37^{o}C. The reduction of GO produced a black suspension that was sonicated for 5 min. followed by centrifugation for 10 min. at 10,000 rpm/min to eliminate bacterial biomass as supernatant liquid. Thus, reduced graphene oxide was obtained as black pellets. This method resulted in highly efficient, large scale production water dispersible reduced graphene oxide by eliminating the use of toxic chemical reductants. Therefore, *E. coli* based reduction of GO presented an eco-friendly protocol. Similarly, an inexpensive and environmentally-benign synthesis of microbially reduced graphene oxide was also reported by Wang and his research group using *Shewanella oneidensis* MR-1 cell culture. Consequently, it is quite obvious that the bioproduction of graphene or reduced graphene oxide has gained great attention over the past few years owing to the simplicity, eco-compatibility, cost-effectiveness and sustainability of these methods.

CONCLUDING REMARKS

The superlative and desirable characteristics of graphene and its derivatives, including large specific surface area, high chemical stability, extraordinary

electrical and thermal properties, high intrinsic mobility, unique optical properties and enormous mechanical strength, have rendered them as the most useful carbonaceous nanomaterials. Considering the wide scope of these materials, several researchers from time to time have immersed themselves in developing simple, sustainable and efficacious synthetic strategies for graphene synthesis. In this chapter, we have summarized some of the most widely employed methods for fabrication of graphene and its derivatives. Several methods including exfoliation, unrolling or unzipping of carbon nanotubes, electric arc discharge method, laser ablation technique, oxidative exfoliation-reduction of graphene oxide, chemical vapour deposition, epitaxial growth, template synthesis, pyrolysis, substrate free synthesis, total organic synthesis, and biological methods have been used for efficient synthesis of high quality graphene and its derivatives. However, despite the rapidly expanding research in the field of graphene chemistry and availability of a large spectrum of methods, there are still a few challenges that need to be addressed for industrial scale synthesis of graphene. For instance, most of these methods largely yield few layer graphene. Scalable synthesis of monolayer graphene is still an area that needs to be worked upon. From economic perspective, designing of inexpensive modus operandi is the need of the hour for commercial graphene production. Also, eco-friendly graphene synthesis which minimizes the release of toxic gases, makes use of benign solvents and precursors, energy intensive protocols, and avoids further processing should be encouraged so at to reduce adverse impact on our environment. Overall, it can be said that in order to realize the dream of industrialization and commercialization of graphene and its derivatives, fabrication of scalable, reproducible, economically compatible and benign synthetic methods is of utmost significance. On a positive note, it is worth mentioning that the pace with which the graphene research is growing, it is quite certain that in near future a plethora of improved methodologies will be accessible for manufacturing of graphene with promising applications in our day to day life.

LIST OF ABBREVIATIONS

2-D	Two-dimensional
3-D	Three-dimensional
AC	Alternating current
APTES	3-Aminopropyl triethoxysilane
CNT	Carbon nanotubes
CTAB	Cetyltrimethyl ammonium bromide
CVD	Chemical vapour deposition
DC	Direct current

DMF	Dimethyl formamide
GO	Graphene oxide
HOPG	Highly oriented pyrolytic graphite
LB	Luria-Bertani
MMS	Mercury/Mercury (I) sulfate
MWCNT	Multi-walled carbon nanotubes
OMP	Organophilic montmorillonite
PAC	Polycyclic Aromatic Hydrocarbon
PANi	Polyaniline
PMMA	Polymethyl methacryalte
PVC	Polyvinyl chloride
PVP	Polyvinyl pyrrolidine
rGO	Reduced graphene oxide
SWCNT	Single-walled carbon nanotubes
TMOS	Tetramethoxysilane
UHV	Ultra high vacuum

CHAPTER 4

Characterization Techniques for Graphene-Based Materials

Vickramjeet Singh[1] and **Ramesh L. Gardas**[2,*]

[1] *Department of Chemistry, Dr B R Ambedkar National Institute of Technology, Jalandhar-144011, Punjab, India*

[2] *Department of Chemistry, Indian Institute of Technology Madras, Chennai - 600 036, India*

Abstract: Graphene bearing 2D (dimensional) layer of carbon atoms bonded in sp^2 hybridized state are only 1 atomic-scale thick. However, the graphene can be extended along the horizontal dimension. The alternate double bonds leading to perfect conjugation with sp^2 hybridization are exhibited in the hexagonal structure (*honeycomb*) of graphene. Theoretically and experimentally, the thicknesses of graphene have been determined and are in the nano-meter range. The extraordinary mechanical and electrical properties exhibited by such a 2D material have inspired scientists for device fabrication methodologies that can shift the synthesis from lab scale to large scale. It is considered the strongest material on earth, almost 100 times stronger (*i.e.*, strength) than the best steel. Since graphene is only 1 atomic-scale thick and transparent, the characterization of graphene is complex but essential. The thickness down to one atomic layer in graphene can be identified by the light interference causing color contrast. Thus, optical microscopy-based methods enable the identification of graphene or its derivatives; on the other hand, Raman spectroscopy, which is sensitive to molecular bonding and geometric structure, is commonly employed for the quality determination of graphene-based materials. In this chapter, various characterization techniques are discussed, enabling the characterization of graphene and graphene-based materials (GBMs).

Keywords: Characterization, Fourier-transform infra-red Spectroscopy (FT-IR), Graphene, Graphene Sayers, Graphene Oxide, Optical Microscopy, Raman Spectroscopy, Reduced Graphene Oxide, Scanning Tunneling Microscope (STM), Transmission Electron Microscope (TEM), X-ray Shotoelectron Spectroscopy (XPS).

1. INTRODUCTION

Graphene is a 2D nano crystallite material composed of a single carbon atom layer packed in a hexagonal arrangement (honeycomb) with alternating single and double bonds [1, 2]. The sp^2 hybridized state of carbon atoms has π-bonds (out-o--plane) responsible for conduction (delocalized π-electrons) and weak interaction between graphene layers [1, 2]. The strongest bond in this carbon allotrope is the in-plane C-C bond [2, 3]. The graphene is thus a 2D semiconductor with zero band gaps or nil band gap energy, *i.e.*, having a minor overlap among the conduction and valence bands [2, 4]. While maintaining the sp^2 hybridization, graphene sheets can be rolled up to make materials with dimensions as 3 D (graphite), 1 D (nanotubes), and 0D (fullerenes) [5]. Since graphene is 1 atomic layer thick, the first report of graphene discovery (structural analysis) was still based on optical microscopy [4, 6]. The ease of analysis by the visualization using an optical microscope is possible for graphene synthesized by mechanical peeling and transferred on a few layers of thick SiO_2 (onto a silicon surface) [6]; however, when deposited on cleaned Si surfaces, this visualization of graphene is lost [6]. The graphene-based materials (GBMs) can be single or multi-layered, graphene oxide, graphene reduced oxide, graphene ribbons, and graphene nano sheets [1, 6, 7]. Graphene with various layers or GBMs can be characterized by a number of techniques, and in this chapter following techniques are being discussed:

1. Optical Microscopic techniques

2. Raman Spectroscopy

3. FT-IR Spectroscopy

4. X-ray Photoelectron Spectroscopy

5. Thermogravimetric Analysis

2. OPTICAL METHODS

As mentioned above, optical methods can be used to characterise graphene synthesized by mechanical peeling unless the graphene is pasted onto a clean Si substrate [6]. The graphene layers onto a SiO_2 substrate can cause light interferences, so the color and the contrast depend upon graphene layers [3, 6, 8, 9]. Besides SiO_2-based surfaces, other substrates for supporting graphene layers that can be visibility distinct are polymethylmethacrylate and silicon nitrite (Si_3N_4) [3, 6, 8, 9]. Mechanical exfoliation may form flakes of various thicknesses; the image of graphite on SiO_2 substrate (oxide thickness of 500 nm)

Not be distributed or uploaded to anyone or anywhere For personal private use only

is shown in Fig. (**1**) [8]. Besides the optical image, the SEM (scanning electron microscope) and AFM (atomic force microscope) images are also shown in Fig. **1 b** and **c**, respectively. The picture shows the regions having varied thicknesses [8]. The rectangular box (broken lines) in these images indicates the region with a few monolayer thicknesses. The images can be resolved to get a better picture with an electron microscope, such as SEM with better electron detectors [8].

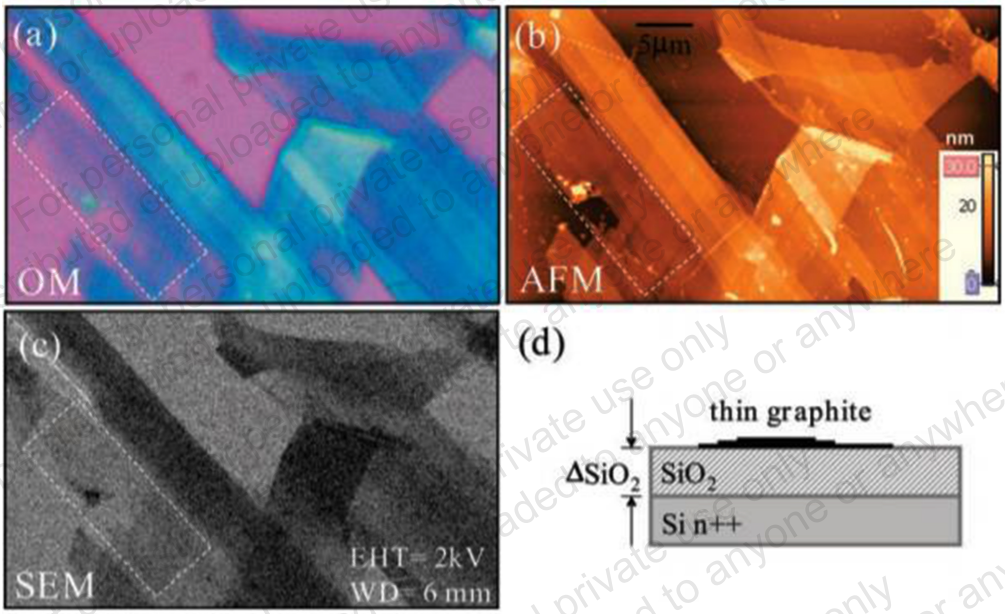

Fig. (1). The image of graphite flake having regions with different thicknesses, as obtained from **(a)** optical microscope (OM), **b)** AFM, **c)** SEM. The graphite was deposited on a Si substrate with a SiO_2 thickness of about 500 nm. Reprinted (adapted) with permission from ref [8]. Copyright (2007) American Chemical Society.

The AFM analysis can directly identify the layer number of graphene, but this technique can damage the crystal lattice while performing the measurement, and the true thickness cannot be estimated [10]. Ni *et al*. [10] developed a method based on contrasting graphene and the substrate onto which graphene layers were transferred. The light reflection makes graphene visible from ten layers down to one layer. Furthermore, experimental data were correlated with theoretical analysis and a good agreement was reported [10]. An analytical expression for determining the number of graphene layers was also provided [10]. Blake *et al*. [3] represented the optical microscopic images of graphene transferred onto the SiO_2 layer. It was demonstrated that the optically visualized contrast depends upon the opacity of graphene and the optical path, that is, the dependence on the SiO_2 layer as well as light wavelength [3]. The images of graphene obtained under

normal light illumination on SiO_2 layers (200 nm and 300 nm) are shown in Fig. (**2**) [3]. It was demonstrated from the images that contrast could be employed as a tool to quantitatively define the number of graphene layers deposited on a suitable substrate (in this case, a Si wafer) [3]. Moreover, the color contrast at different wavelengths of light and SiO_2 thickness is also shown in Fig. (**3**) [3]. The Fresnel theory was applied to show that by using appropriate filters, the contrast could be enhanced for various SiO_2 thicknesses [3].

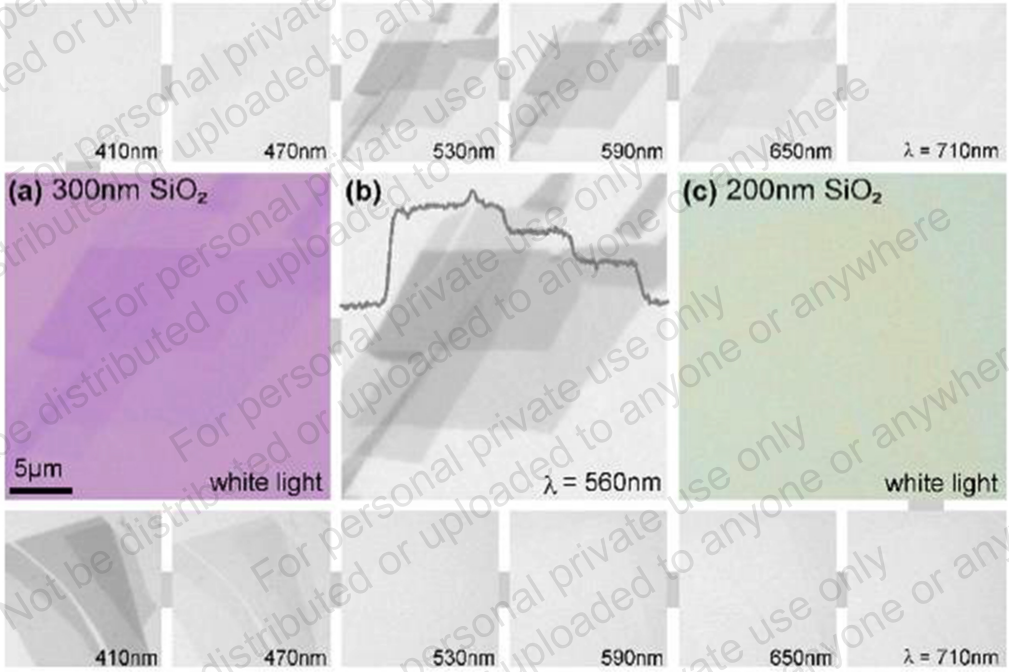

Fig. (2). The images of graphene crystallites **(a)** deposited onto Si wafer (SiO_2 thickness was 300 nm) obtained using normal white light, **(b)** deposited onto Si wafer (SiO_2 thickness was 300 nm) obtained using green light and **(c)** deposited onto SiO_2 (thickness 200 nm) obtained using normal white light, here in image **(c)** graphene is not visible. The images shown above and below those of a, b and c were taken by illumination through various narrow-band filters [3]. Reproduced from ref [3], with the permission of AIP Publishing.

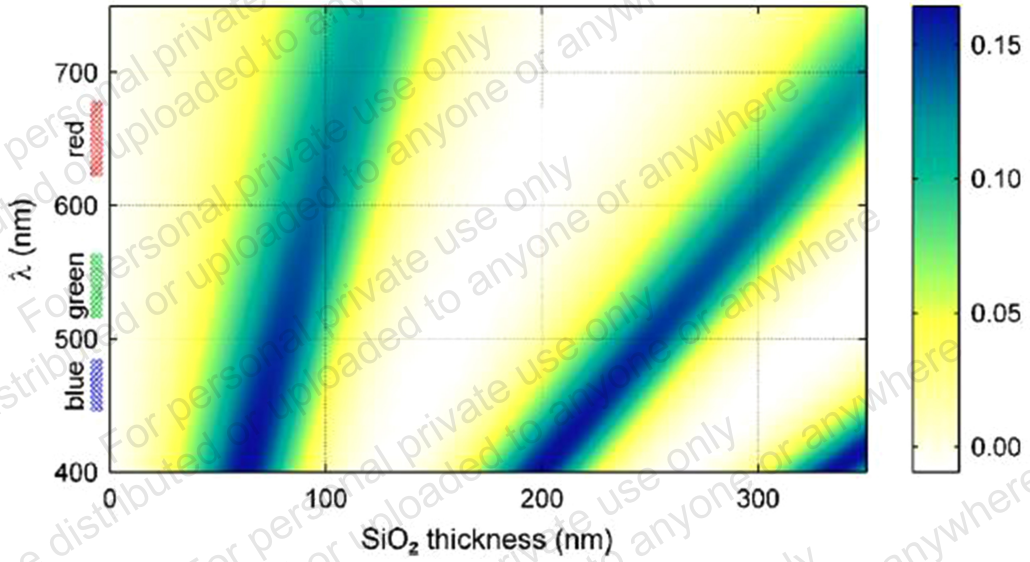
Mechanically exfoliated graphene deposited on SiO_2 (300 nm thickness) was also observed using an optical microscope along with a scanning force microscopy (SFM) micrograph for the selected flakes, as reported previously [11]. The color and contrast were qualitatively correlated to the intensity of light (white to blue to violet light). The number of layers with an uncertainty of ± 1 layer estimated from SFM analysis; the uncertainty arises due to surface roughness and the difference in height between the first layer and the substrate [11]. A methodology was developed by Jia *et al*. [12] by which graphene domains/boundaries can be

optically identified on a surface other than SiO_2 layers. The copper oxide enhances the interference, leading to color contrast, thereby making the visible detection of graphene with an optical microscope possible [12] (see Fig. **4**).



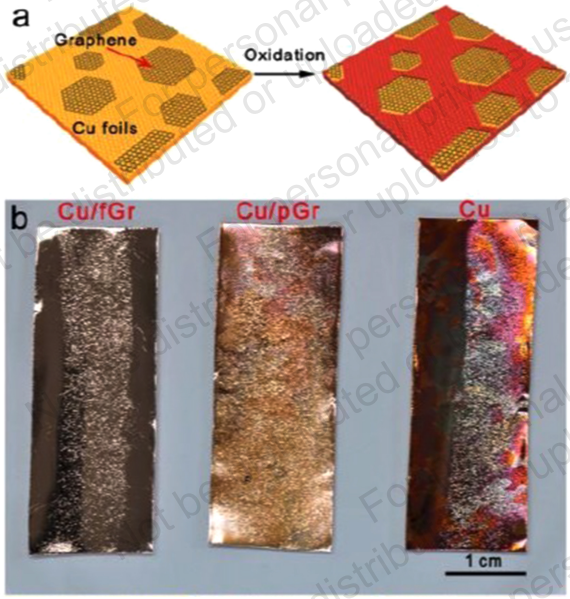


Fig. (3). The plot (colored) depicted by variation in wavelength as well as SiO_2 thickness. The scale in color on the right side depicts the expected contrast [3]. Reproduced from [3], with the permission of AIP Publishing.

Fig. (4). The **(a)** schematic illustration of optical characterization and oxidation of graphene domains deposited on Cu substrate **(b)** pictures of Cu substate (foil) having fully grown graphene (represented as Cu/fGr), partially grown graphene (Cu/pGr), Cu without graphene after annealing at 160 ºC for 6 min. in air. The optical images of **(c)** Cu/fGr, **(d)** Cu/pGr, and **(e)** Cu foil after the annealing [12]. Reused with permission from ref [12]. under Creative Commons license.

Hong *et al*. [13] have visualized graphene deposited on Cu-foil by the area-specific atomic layer deposition (ALD) method. The optical images were shown for graphene on Cu substrate obtained by annealing at 200 ºC and with various cycles of ALD [13]. The underling Cu substrate was oxidized by water vapor, with selective deposition of single-layer graphene. The Al_2O_3 was used as a mask to cover single-layer graphene (SLG) and the area with multi-layer graphene (MLG). The MLG was removed by ion etching, and the copper substrate was thermally oxidized before visualization. The images of graphene on Cu substrate obtained by ALD as a function of time and ALD cycles were reported [13]. Overall, the process is a four-step involving chemical vapor deposition, area selective ALD, treatment with plasma, followed by thermal oxidation [13]. These combinations of surface modifications provide a way to demonstrate the spatial distribution of graphene multi-layers and control the growth and quality evaluation of graphene [13]. The multi-step process was monitored/characterized by TEM, Raman spectroscopy, and SEM [13].

Besides Cu and SiO_2, Ni surfaces have also been used for the growth of graphene multi-layers [14]. The chemical vapor deposition (CVD) method at 900 ºC was employed for graphene formation on polycrystalline as well as single Ni (111) crystals [14]. The thermal annealing rate was modulated for the growth of graphene on polycrystalline Ni. The X-ray diffraction (XRD) spectra collected from single as well as polycrystalline Ni with variable annealing rates and the optical images of graphene are shown in Fig. (**5**). Only mono- or bi-layer graphene was formed on a single Ni crystal [*i.e*., Ni (111)] due to a lack of grain boundaries (interplane) on a single crystal and thus reduction in the nucleation sites [14]. The multi-layer graphene (MLG) was depicted by the dark regions in the optical images, and the light regions depict the bilayer (or monolayer) graphene, and this was confirmed by Raman spectroscopic analysis [14]. The various samples were obtained with slow, medium, or fast annealing rates. It was reported [14] that with an increase in polycrystallinity of Ni, the growth of MLG

was enhanced. Bilayer or mono-layer graphene formed on central regions of larger crystalline grains, whereas the enhanced carbon segregation confined to polycrystalline grain boundaries was responsible for MLG formation [14].

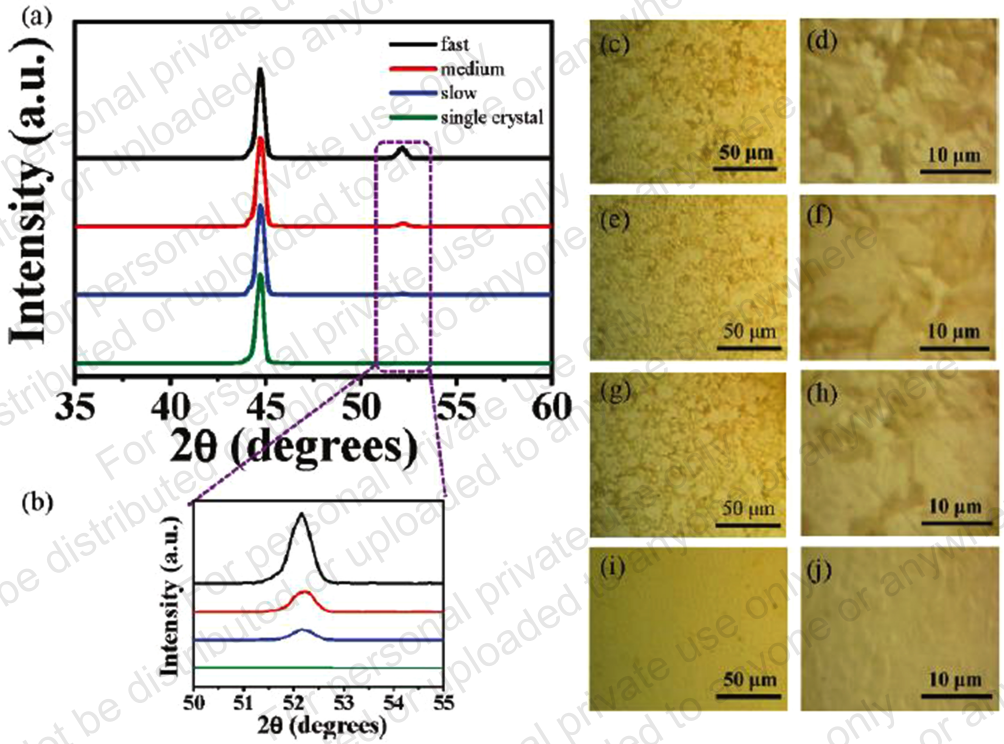

Fig. (5). a) XRD spectra from polycrystalline Ni with variable annealing rates {*i.e.* black (fast), red (medium), and blue (slow)} and XRD spectrum from single-crystal {Ni (111) (green)} after thermal annealing (XRD spectrum is identical for Ni (111) using different annealing rates). **(b)** XRD spectra (Zoomed-in) of peaks at 2θ = 52.16º (that is assigned as Ni (200)). **(c-j)** Optical images after CVD grown graphene on polycrystalline Ni with variable annealing rates {**c, d** (fast); **e, f** (medium); and **g, h** (slow)}; **i,j** optical images after CVD grown graphene on single crystal Ni (111) [14]. The figure has been reprinted (adapted) with permission from ref [14]. Copyright (2010) American Chemical Society.

2.1. Optical Microscopic Analysis

Due to the limited wavelength of visible light, the resolution of an optical microscope is low (~ 200 nm); therefore, to observe the structure at the atomic level after the basic optical microscopic analysis, the most popular tool for the characterization of graphene or graphene derivatives (Go, rGO *etc*.) is based on electron microscopic methods [15]. This way, structural morphology, quality, and crystal structure can be investigated [15]. The commonly used optical microscopic techniques are AFM, TEM or high-resolution electron microscope (HR-TEM), SEM, and scanning tunnelling microscope (STM) [15].

2.2. Transmission Electron Microscope (TEM)

The electrons which are transmitted through a thin sample kept on a TEM grid are analysed in the technique [15 - 17]. The local information at the atomic level about the bulk and surface of a sample is obtained by using TEM. The technique also provides information such as three-dimensional structure, electronic, and chemical properties [16]. In spite of a versatile technique for optical analysis, TEM demonstrates drawbacks such as a small relative area of view as compared to SEM [15, 16]. Very high magnification and a much better resolution down to a group of atoms or even a single atom are provided by HRTEM [15]. The advanced TEM provides various structural and material information as: a) in- real space; or b) reciprocal space or energy space (the spectroscopic mode) [16 - 19].

The C-C bond distance of about 0.142 nm [19] in graphene can be directly resolved by aberration-corrected TEM (AC-TEM), which employs accelerating voltage in the range of (60-80 kV) [16 - 19]. This voltage range is relatively low and avoids beam damage [19]. The better resolution images of graphene and carbon nanotubes were thus recorded by AC-TEM and reported by Suenaga and co-workers [20 - 25]. A lot of new information was provided for various nanomaterials, including graphene [19 - 25]. The image of graphene has been reported by Suenga and Koshino [25]. The TEM-based characterization of carbon-based material is explained in a review by Zhang and Su [16]. The sample preparation is required for TEM analysis; the support film used for materials like carbon nanotubes or graphene can produce a stronger contrast as compared to the sample under analysis [16 - 19]. Thus, various techniques have been employed for sample preparations, such as mechanical exfoliation and transfer of graphene onto TEM grids or CVD on grids [26]. The graphene or GBMs (graphene-based materials) can be synthesized by employing various methods, viz. mechanical exfoliation (top-down), reduction or oxidation of bulk graphite, CVD, and flash Joule heating [2, 26 - 29].

The recent report regarding the scalable synthesis of graphene from cheap sources (tyres, coal, carbon black, waste food) in a short period of time employs a flash joule heating process [30]. The process involves the heating of precursor carbon material above 3000 K for a period of < 100 ms. The heating is performed by means of high voltage electric discharge between two electrodes forming turbostratic graphene [30]. The graphene derived from the process was shown to have single-layer graphene, also graphene showing Moire pattern (interference pattern) [30]. The graphene thus produced does not require a purification step and, in addition to TEM, is also characterized by Raman spectroscopic technique [30]. Ding *et al*. [31] have reported the green synthesis process to obtain graphene *via* a

one-pot synthesis process. The precursor used is an alkaline mixture with lignin (called as black liquor) [31]. The graphene, called black liquid converted graphene (BL-G) with thickness between one to three atomic carbon layers, was obtained [31]. The BL-G obtained *via* this green process has a hexagonal lattice structure and thickness similar to reduced graphene sheets fabricated by the conventional chemical process [31]. The TEM and high-resolution TEM (HR-TEM) images of BL-graphene were recorded to analyse synthesized graphene. The BL-G was spin-coated on a flexible substrate with decreased transparencies and enhanced conductivity [31].

The remarkable properties of graphene oxide (GO) have led to extensive research on GO synthesis, characterization, and application [32 - 36]. The monolayer graphite oxide layer is considered as GO, typically fabricated by oxidation of graphite and then stored in dispersed form or as agglomerated (dried) form [36]. Wilson *et al*. [27] have performed the structural analysis of GO by electron microscopy. It was concluded that the hexagonal symmetry was maintained with order and the C-C bond length of the pristine (unmodified) graphene sheet. The GO was used as an underlying film for the study of the structure of macromolecules, and this has become possible as GO was stable under the electron beam and demonstrated transparency in the electron beam [36]. Thus, GO can be used as a TEM grid [36].

However, the structural characterization of GO is challenging owing to its non-stoichiometric structure and the structured dependency on the fabrication process [37, 38]. Moreover, surface contaminants (oxidative debris [39], amorphous airborne hydrocarbons [40]) influence not only the surface properties but also the chemical structure and defect density [38 - 41]. The image in the TEM detector may not be a direct image showing atomic position; rather can be a modification of the wave coming from behind the sample by the optical (electron) system of microscope or modification of incoming electron wave by the under studied sample [42]. In such a case, aberration-corrected TEM is employed [38, 42]. The direct image can be obtained for graphene but still cannot be successful for GO or GO with contaminants [38, 43]. Dave *et al*. [38] demonstrated a method to remove contaminants for a much better atomic resolution of GO. The *in-situ* heating (up to 700 °C) enables the elucidation of GO structure [38], which otherwise inhibits the sample imaging by adsorbed surface contamination [38].

2.3. Scanning Tunnelling Microscope (STM)

The graphene layers stack in a number of arrangements in graphite; the layer arrangement is described in detail by Mayer, Li and Andrei [43]. The atoms marked A in the top layer can reside above the B atoms of the lower layer in such

a manner that three stacking modes can occur: AA stacking, AB stacking (Bernal stacking) and twisted stacking (giving Moiré pattern). In the AA stacking, layers are stacked in such a way that all the carbon atoms of one layer are on top of the other carbon atoms; Bernal stacking or AB type stacking is done with a shifted second layer such that A atoms reside on top of atom B of the layer, which is twisted by some degree [43 - 45]. The twisted or rotated stacked layers form the Moiré pattern [43 - 45]. Lucian *et al*. [46] employed home build low-temperature STM to study the graphene layers. They employed CVD at ambient pressure for the growth of graphene layer on polycrystalline films. The graphene layers were mechanically supported by spin-coated polymethyl methacrylate (PMMA) layers; afterward, the graphene layers were transferred onto the TEM grid for analysis. It was demonstrated that the electronic properties (low energy) of twisted graphene layers were managed by Dirac femion [46].

The twisted graphene layers (TGL) (particularly bi layers) have also been analysed with an optical microscope, and it was demonstrated that various coloured regions variable in shape and size are present in a given sample [47]. The red-, blue-, and yellow-colored domains are shown in Fig. (**6**) [47]. The methodology for bilayer fabrication is depicted in Fig. (**6a**) and Fig. (**6b**) represents the coloured domains. Briefly, the fabrication involves the growth of graphene films onto Cu support by CVD at ambient pressure, then transferring the layers onto Si/SiO_2 substrate by a wet process using PMMA protection layer and etching process [47]. The process was repeated to grow a graphene bilayer onto an already transferred graphene layer supported on SiO_2/Si [47]. The distinct colored regions occur without the use of any filters; as shown in Fig. (**6b**), the graphene layers were annealed and chemically treated (solvent cleaning) to modify the extent of the color domains, but there is no change in colored regions suggesting that the colors do not produce by impurities or residues [47]. The colored regions are observed in the bilayer but not by the neighbouring single layer [47].

The scanning tunnelling spectroscopy provides tunnelling conductance as a function of the quantity considered proportional to the density (local) of states (DOS). This quantity is bias voltage [48, 49]. The tunnelling spectrum obtained in zero magnetic field and low temperature is obtained for graphene flakes and graphite. A V-shaped curved is obtained for graphene DOS in the proximity of the Fermi level and reaches a minimum (at zero bias voltage) at Dirac point [48, 49]. The graphene flakes obtained after mechanical exfoliation of highly oriented pyrolitic–graphite (HOPG) are obtained as loosely bound graphene after exfoliation on graphite surface [48]. The STM images of the graphene layers were recorded as well. It was concluded that graphite as a substrate for the growth of graphene could be used for studying the intrinsic properties of charge carriers in graphene [48].

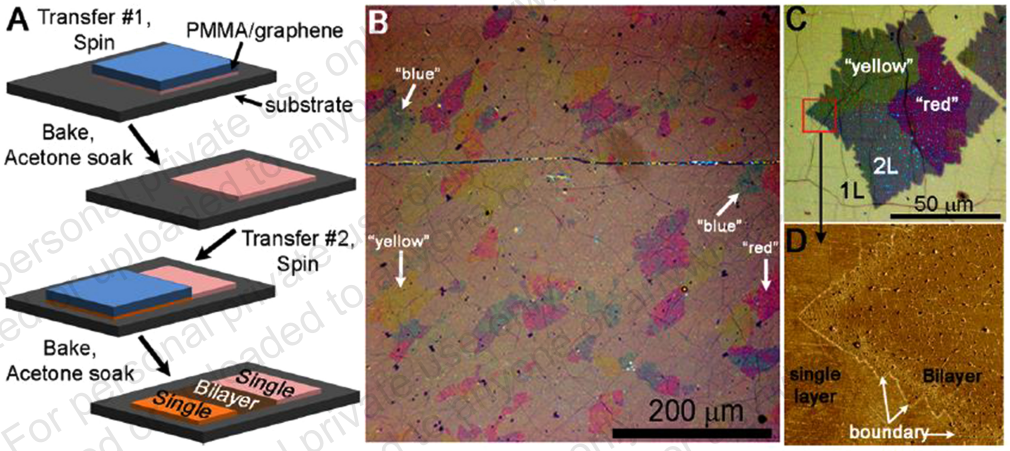

Fig. (6). The fabrication as well as characterization of stacked graphene films. **(a)** Schematic process for bilayer graphene preparation starting from single-layer CVD graphene films. **(b)** Images (Optical microscope) of a twisted bilayer graphene (TBG) film. The colored domains {"red", "blue" and "yellow") are depicted. **(c)** Sample showing top (second) graphene layer is only a partial layer, forming single-(1L) and bi-layer (2L) regions. **(d)** AFM images (15x15 μm^2) depicting the boundary between the single-layer and bilayer region highlighted by the red box in figure **(c)** [47]. 3. RAMAN SPECTROSCOPY

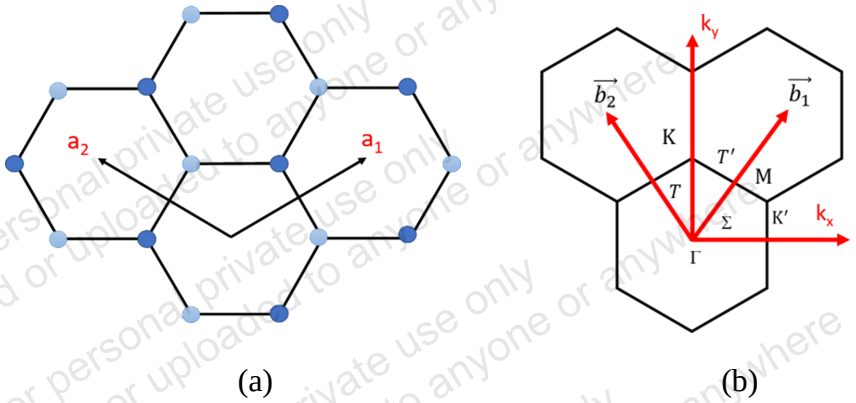
The identification of graphene or graphene-based materials has also been performed extensively by Raman spectroscopic technique [50, 51]. Simultaneous study of vibrational and electronic properties of graphene-based materials (GBM) is obtained from Raman spectroscopy [50, 51]. It is a reliable, rapid, non-destructive, sensitive analytical technique that provides high resolution and better precision [51 - 53]. The technique is based on the Raman Effect involving the Stokes process (absorption) and emission of phonons (anti-Stokes process) [50, 51]. The technique is sensitive to molecular structure and bonding in the molecule. The Raman bands obtained for graphite are influenced by the defect, flakes, layer of flakes, functionalization, doping, *etc* [53, 54]. Since the band gap is negligible in graphene, the incident wavelength resonates information regarding electronic and atomic levels [53, 55]. The position of the peaks, intensity and shape (of Raman band) varies with flake size, degree of doping, oxidation, number of layers, *etc* [51 - 55]. Thus, Raman spectroscopy quantitatively provides information that is mostly in agreement with microscopic analysis data [53 - 55].

The technique, which is based on Raman Effect, involves the phenomena in which light of wavelength (750-850 nm) excites the molecules in the sample. The incident light interacts with the sample, causing light to be reflected with different

frequencies (or wave numbers) [53 - 55]. The wave number change occurs due to molecular rotations and vibrations in the sample [55, 56]. The modulated frequency provides information regarding the molecular structure of the sample [55, 56]. In the case of graphene with a negligible band gap, the incident wavelength resonates, providing atomic and electronic information. Thus, peak shape, intensity, and position vary with oxidation, disorder, doping, layers and flakes of graphene [54, 55].

The absorption or emission of phonons that are observed in Raman spectroscopy occurs owing to the interaction between incident radiation (light) and vibrations causing energy shift. The shift causes a change in wave number of emission or absorption [50, 57]. The energy difference between absorption and emission is known as the Raman shift [58]. When an electron scattered by phonon leads to first-order Raman scattering or the scattering can be of higher-order (second or more), involving scattering by two or more than two phonons [58, 59] and these provide a lot of information regarding the phonon coupling in the studied material [58]. Thus, Raman spectroscopy is effectively used to evaluate carbon nanostructures ranging from amorphous carbon, and carbon nanotubes (CNTs) to graphene or GBMs [58]. Jorio *et al*. [60] have shown the Raman spectra of various carbon-based materials. The similarities among the spectra, as well as differences between the spectra, help to study various carbon allotropes [15].

For understanding the characterization process for graphene or graphene-based materials, the graphene with honeycomb structure (Fig. **7a**) having sp^2 hybridization [60 - 64] of carbon and the reciprocal space unit cell depicting the first Brillouin zone (phonon dispersions of graphene, Fig. (**7b**) are shown in Fig. (**7**). The monolayer graphene showing hexagonal symmetry belongs to D^1_{6h} (space group *P6/mmm*) [60, 61]. Graphene having six normal modes (2 are double degenerate) and 2 atoms per unit cell at the Brillouin zone (Γ) center with (Γ) = $A_{2u} + B_{2g} + E_{1u} + E_{2g}$ [50, 62]. The B_{2g} phonon is Raman and IR inactive, while E_{2g} phonons are active, showing Raman spectra [50]. In the case of graphene, the phonon dispersion (six phonon branches shown in Fig. (**7b**) from the non-equivalent 2 carbon atoms present in the unit cell [60, 63]. The characteristic peaks in Raman are of two types called the G (~ 1582 cm^{-1}) and the G' bands (~ 2670 cm^{-1}) [58]. The in-plane sp^2 C-C vibration of carbon atoms (C-C in-plane vibration) leads to the band called as G band (first-order Raman mode) [50, 51, 58, 60]. The G band is related to doubly degenerate phonon modes, namely iTO (in-plane transverse optic) and LO at the Brillouin zone center Γ point, with the E_{2g} symmetry [51, 58, 60]. The LO stands for longitudinal optic [51, 64]. The iTO and iLO phonons are causing the Raman active bands in the graphene [64]. The second-order Raman scattering *i.e*., G' band involves inelastic inter-valley scattering with iTO phonon close to the K point [51, 64].



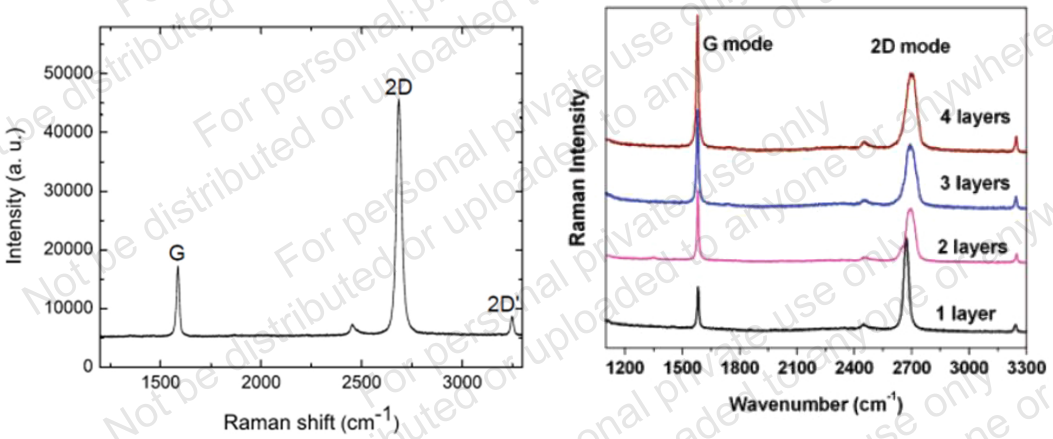


Fig. (7). (a) Monolayer graphene from a top view showing the unit vectors a_1 and a_2 and inequivalent atoms A and B; **(b)** reciprocal space unit cell depicting the first Brillouin zone (BZ) with high-symmetry points and lines. Reciprocal space coordinate axes are K_x and K_y (primitive vectors) [64].

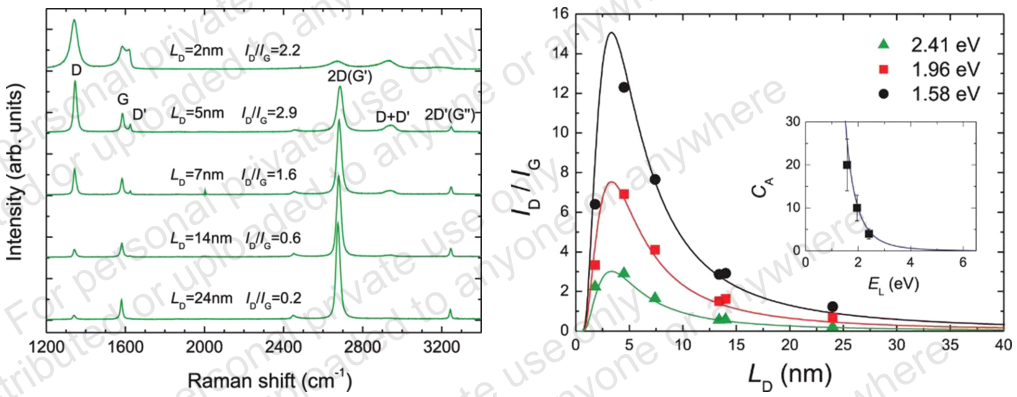
The G' band is also known as 2 D mode [50]. The G, G', and D peak positions are used to study graphene layer or doping in graphene [50]. The GO obtained from oxidation of graphite having sp^3 hybridized carbon is characterized based on G and D bands [50]. The D and D' peaks are Raman bands (second-order); here D band is inter-valley scattering with iTO phonon and defect; in other words, it arises due to disordered C atoms [50, 51, 53]. Whereas D' band is intra-valley double resonance scattering phenomena with iLO phonon and the defect [50, 51]. So, the G band occurs due to bond stretching of carbon sp_2 atoms both in ring and chain compounds, whereas the D peak appeared owing to the breathing mode of the sp^2 hybridized atoms in the ring [55, 65, 66]. Since D mode is known to occur by disorder or defects in the graphene-based materials, the ratio of D band to G band intensities (I_D/I_G) denotes the disorder/defect level in graphene synthesis [53, 67]. The 2D band is a G' band but has a frequency twice that of the D band [51]. The 2D band is present in both graphite and graphene [53]. The D and G' band peaks change as the excitation wavelength of the laser changes [51, 53, 60].

The prominent G' (second-order) band ~ 2700 cm^{-1} is produced by two phonons which is the iTO (in-plane transversal optical) phonon close to the K point in the Brillouin zone [60, 63]. This phonon displays strong electron-phonon coupling and produces a prominent G' band [60, 63]. In graphene, other phonons can produce similar scattering processes, causing various smaller peaks to appear in Raman spectra [60, 68]. Tuinstra and Koenig [66] performed the Raman spectroscopic analysis of single-crystal graphite and other graphite materials. The peaks at ~1580 cm^{-1} are assigned to E_{2g} and at ~1350 cm^{-1}, to A_{1g} breathing mode

[66]. The former high-frequency peak and the mode at Brillouin Zone (BZ) boundary K are known as G and D peaks, respectively [66, 69, 70]. The Raman spectrum of graphene (crystalline) on SiO_2/Si substrate is shown in Fig. (**8a**); the excitation laser with 514.4 nm was employed [64, 68]. The spectrum has two Raman bands at 1580 cm^{-1} (G band) and another one at 2700 cm^{-1} {the G' band or termed at 2D band} [64, 68, 71]. The number of graphene layer influences the intensity of the 2D band, which is approximately four times as compared to the G band in the case of crystalline graphene single-layer atoms [10, 64, 68, 72 - 75]. The number of layers in graphene increases, causing variation in an electronic environment, and this change occurs due to interactions among adjacent layers [53]. This consequently results in the broadening of 2D peaks and decreasing of the peak intensity [53], as shown in Fig. (**8b**). After a few layers (five), graphene and graphite Raman spectra are indistinguishable [53, 68]. The D band is weak, and the presence of defects in graphene nanosheets makes the D band appear in the spectrum [64]. The intense D peak is observed for amorphous carbon isotopes, which are absent in graphitic material [64].

(a) (b)

Fig. (8). The Raman spectra of **a)** crystalline graphite, **(b)** few layer graphene. Reproduced/reprinted (adapted) from refs [10, 64].



Ni *et al*. [10] employed a 532 nm excitation source for recording Raman spectra of graphene having different staked layers [10]. The sharp 2D peak is observed for single-layer graphene, which is distinguishable from the 2D band of multi-layer graphene. But in the case of graphene with 2 to 4 layers, the difference in 2D peak is not noticeable, but a visible difference is observed in G band intensity [10]. The appearance or disappearance of D peaks corresponds to the defects or imperfections in the hexagonal sp^2 carbon network [60]. The Raman spectra are

shown for amorphous carbon materials with or without high-temperature treatments, with D band peaks appearing in the spectra having different peak widths and intensities [60]. With few defects in the structure will exhibit D, and in the case of crystalline ordered graphene or graphite, the D band was missing [60]. Luong *et al*. [30] fabricated the high-quality graphene by the flash Joule heating (FJH) process and observed that the I_{2D}/I_G is greater than 10. The D band with extremely low intensity is observed, indicating a low defect concentration [30]. The ratio I_{2D}/I_G was as high as 17 for graphene obtained from carbon black by the FJH process and was reported to be the highest value for any form of graphene [30]. This is due to the extremely high temperature achieved for graphene fabrication by the flash process [30].

Cancado *et al*. [70] studied the Raman spectra of single-layer graphene samples with various defect densities. The defect was created by the bombardment of the sample by Ar^+ ions. The Raman spectra of various SLG bombarded with different doses of Ar^+ ions are shown in Fig. (**9**). Thus, the measure of defects (point-like) in graphene was evaluated from the I_D/I_G ratio by Raman spectroscopy using different excitation laser energies [70].

The one-dimensional defects (or the amount of border) with respect to the crystalline area give the degree of disorder in a nano-crystallite and the measurement of L_a [70]. In the case of zero-dimension point-like defects, as in graphene, L_d is the distance between defects [70, 75]. Various methods can quantify the measure of the amount of disorder, *i.e*., L_d, by using Raman spectroscopic analysis [70, 75]. Thus, the influence of L_d on peak frequency, width, integrated area and intensity has been studied [70, 76, 77]. In Fig. (**9a**), the peaks at 1580 cm^{-1} and 1350 cm^{-1} correspond to G and D bands, respectively [70]. The strongly dispersive intervalley double resonance process having excitation energy due to Kohn Anomaly at K gives rise to the D peak [70]. The intervalley process can also occur by connecting the two points which belong to the same cone around the K or K' [78]. Thus, giving a peak at ~1620 cm^{-1} in a defective sample is obtained using a laser at 514.15 nm [70]. The second-order 2D peak appears as a single peak in graphene but breaks into four peaks in the case of BLG (bilayer graphene), indicating the electron band structure evolution [68, 70, 79]. Again, the second-order peak of D' known as 2D' and the 2D peak do not require any defects for their activation and are found in the Raman spectra [70]. However, the peak corresponding to ~ 2940 cm^{-1} (D + D') requires defect activation, and this peak is a combination of phonons having dissimilar momenta at K and Γ [70]. In Fig. (**9b**), the plot of I_D/I_G*vs.* L_D is represented [70]. The ratio increases with a decrease in L_D and reaches maxima at L_D ~ 3 nm and reaches a minimum (zero) at L_D < 3 nm [70]. Thus, Raman spectroscopy has been employed for the analysis of defects in graphene and related materials [80]. The detailed application of Raman

Spectroscopy is provided in the reference [51]. Kumar and Pattammattel [53] highlighted a few limitations and opportunities for errors in employing Raman spectroscopy; these are summarised previously in the literature [53]:

(a) (b)

Fig. (9). (a) Raman spectra of ion bombarded SLG with different L_D (measured at laser excitation energy, E_L = 2.41 eV and wavelength, λ_L = 514.5 nm). The L_D (distance between defects) is independently measured as per ref [70, 75]. The I_D/I_G values are shown for each spectrum. The notation, such as in the parentheses [2D(G´)], indicates two commonly used notations for the same peak (2D and G´); and **b)** I_D/I_G for all SLGs and E_L [70, 75]. The inset figure is the plot of C_A *vs.* E_L. Reprinted (adapted) with permission from ref [70]. Copyright (2011) American Chemical Society.

A) The sampling for Raman analysis is crucial; for instance, the spectroscopic analysis of exfoliated graphene samples can estimate the graphene layer. The transfer of exfoliated samples on glass slides can lead to the rest of the sheets, thus providing a rough evaluation of the number of layers [53]. The samples (films) fabricated from various stock solutions under dilute conditions can provide a better way of sample analysis. However, they may encounter problems related signal-to-noise ratio [53].

B) The particle size estimation (formed by exfoliation) from Raman analysis should be complemented with absorption spectroscopy and microscopic studies [53].

C) During spectroscopic analysis, samples can undergo photoreduction, as in the case of graphene oxide, influencing the conclusions drawn [53]. By reducing laser excitation energy (laser power) or by defocusing, the damage caused to samples can be minimized, and the same can be judged by optical analysis using an optical microscope [53].

4. FT-IR SPECTROSCOPY

FT-IR spectroscopic analysis is one of the efficient approaches for the detection of functional groups in the molecule [53]. The modification or functionalization of graphene or graphene oxide can be analysed by IR spectroscopy along with other spectroscopic techniques such as NMR, and XPS [6, 53, 81]. The 2D hexagonal arrangement of sp^2 hybridized carbons atoms is present in graphene [82, 83]. In the FTIR spectrum, no significant peak due to any functional group is observed [82, 83]. But in the case of graphene oxide, IR spectra provide information regarding -COOH, -OH, C-O and C=O functional groups, as shown in Fig. (**10**) [53, 84]. Fig. (**10**) shows spectra for crystalline graphite, GO and rGO [84]. The in-plane stretching vibration of C=C in graphite appears at ~1500–1600 cm^{-1} [81, 84]. In the case of GO, -OH peak appears at 3162 cm^{-1}, C=O peak at 1710 cm^{-1}, and for alkoxy and epoxy groups, the peaks are at 1050 cm^{-1} and 1220 cm^{-1}, respectively [53, 84]. The functionalization of graphene can be performed by a number of reagents, including amino acids, carboxylic acids, polymers, phosphates, *etc* [73, 84 - 87].

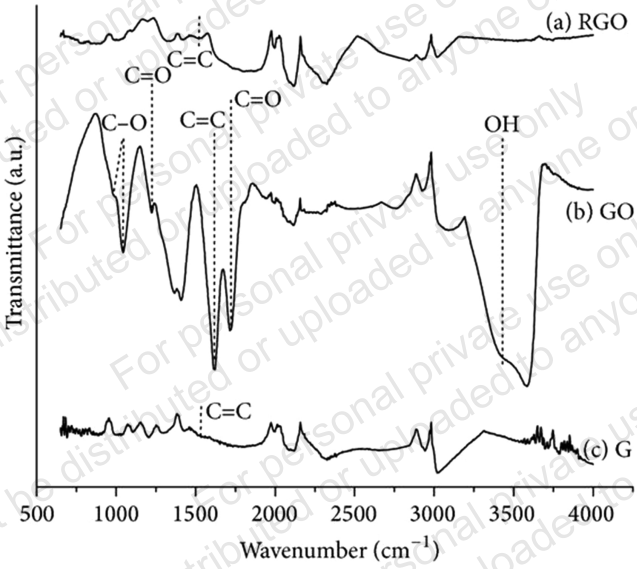


Fig. (10). The figure represents the IR spectra of **(a)** (RGO), **(b)** graphene oxide (GO), and **(c)** pure graphite (G). Reproduced with permission from ref [84]. under Creative Commons Attribution License.

Mittal *et al*. [88] performed thermal oxidation of graphene (a few layer) in the presence of oxygen, and the oxidized graphene was analysed by FT-IR spectroscopic technique. The attached oxygen groups onto the surface of oxidized graphene (called porous graphene) were confirmed by the peaks at 3418 cm^{-1} for -OH; similarly, the peaks at 1726 cm^{-1}, 1096 cm^{-1}, and 915 cm^{-1} ascribed to -COO-,

-C-O-, and -C-O-C- groups, respectively [88]. Kuila *et al*. [89] employed a green approach to reducing for the reduction of GO to rGO, by using carrot root (endophytic micro-organisms in the carrot root). The partial reduction of GO to graphene was confirmed by X-ray photoelectron and FT-IR [89]. The C=O stretching peak and -O-H deformation peaks at 1728 cm^{-1} and 1395 cm^{-1}, respectively, decrease significantly after carrot-assisted reduction of GO [89]. The intensities of epoxy and alkoxy C-O stretching peaks were unchanged after reduction, but the peaks' position was significantly altered [89], owing to a partial reduction of GO. New peaks due to carotene present in carrots appear at 2928 cm^{-1} and 2851 cm^{-1} [89].

Acik *et al*. [81] performed *in situ* transmission IR absorption analysis of GO during vacuum thermal annealing (temperature 60-850 ^{o}C). In this work, Acik *et al*. [81] have reported that the peak assignments (identification of chemical composition) in IR of GO are difficult and challenging due to conjugation and proximity effects. Modified Hummer's method was used for the fabrication of GO and analysed by the peaks at 3000-3600 cm^{-1} of hydroxyls C-OH (-COOH, H_2O contribution), ketones C=O at ~ 1750-1850 cm^{-1}, carboxyls (COOH) at ~ 1600-1750 cm^{-1}, in-plane C=C stretching at ~ 1500-1600 cm^{-1}, C-O-C epoxide peaks at ~1280-1330 cm^{-1} and 800-900 cm^{-1}, along with weak contributions by all these species in the region 900-1500 cm^{-1} [81]. The possible IR peak assignments of functional groups needed for the characterization of graphene-based materials are reviewed by Tucureanu *et al*. [82]. Since the IR analysis is complementary to other spectroscopic analyses, *e.g*., XPS, NMR, *etc*., the characterization of GBMs by XPS analysis is discussed in the next section.

5. X-RAY PHOTOELECTRON SPECTROSCOPY (XPS)

The characterization of surface functionalities is done using X-ray photoelectron spectroscopy (XPS). This is a quantitative technique for the evaluation of surface chemistry, the chemical and electronic state of elements, and also the elemental composition [43, 90 - 92]. The X-ray beam irradiates the material of interest; the surface generates a spectrum of electrons with characteristic kinetic energy [92]. The number and kinetic energy of released electrons are measured in XPS [93]. Thus, XPS peaks with characteristic binding energies are obtained by the various elements exposed to the X-ray beam [92]. The peaks provide information regarding electronic configuration within atoms [92]. The technique is based on the photoelectric effect [93], and for obtaining XPS spectra, the sample is irradiated with X-ray beams [91 - 93]. The law of energy can be used to understand the working principle of the XPS technique as [91 - 93]:

$$E_p = E_{ke} + \varphi + E_{bind} \quad \textbf{(1)}$$

In the above eq. (1), E_p, E_{ke}, φ, and E_{bind}, represent the energy of the incident X-ray radiation (*i.e.*, of incident photons), the kinetic energy of the photon emitted core electrons, the part of energy absorbed (work function), and ionization energy (binding energy) in eV, respectively [91 - 93]. So, the binding energy is calculated from the above equation [91, 93]. The photons of incident radiations eject core-level electrons from the atoms, and the kinetic energy of electrons depends upon the binding energy in the atoms and the elements from which electrons are ejected [91, 93]. The ejected electrons are collected from the uppermost 3 nm to 7 nm part of the material under study [91, 93].

XPS has been employed to characterize GBMs, GO, and rGO [53, 91, 93]. The representative binding energy of C1s, depending upon the chemical environment, is detected around 285 eV [53, 90]. The various C1s components of graphene with binding energy are shown in Table **1** [53].

Table 1. The binding energy (eV) of C1s components in graphene [92 - 97].

State	C1s Binding Energy (eV)
C-C	284.9-285.6
C=C	284.3-284.6
C=O	287.9-288.3
C-OH	285.4-286.7
C-O-C	285.6-286.9
COOR/COOH	288.3-289.4
O=C-O	288.5
O-C-O	285.6-286.9
π-π*	290.5-291.2
C-H	285.3
C=O	289
C-N (sp^3 N)	283.7
C=N	286.8

As shown in Table **1**, the common chemical state of carbon along with oxygen is used to identify or distinguish graphene from GO or rGO, heteroatom doped graphene [92 - 97]. The GO is rich in elemental oxygen, so in XPS analysis strong oxygen-bearing C1s peaks are observed [92]. Among the oxygen-bearing groups in GO, such as C-O, C=O, O-C=O, the most dominating XPS peak is C-O [92,

98]. Yu *et al*. [98] have reported improved Hummer's method for fabrication of GO in a high yield. The fabricated GO was characterized by various techniques of spectroscopic (FTIR, UV, XPS, Raman) [98]. XPS spectra for the fabricated GOs are shown in Fig. (**11**), in which the GO2 is the GO fabricated by their methodology, and GO1 is fabricated by improved Hummer's method reported by Kovtyukhova *et al*. [99]. Few XPS spectra indicate a strong peak of C=C [92 - 97, 99], and some report a strong main peak of the C-O bond [92, 98].

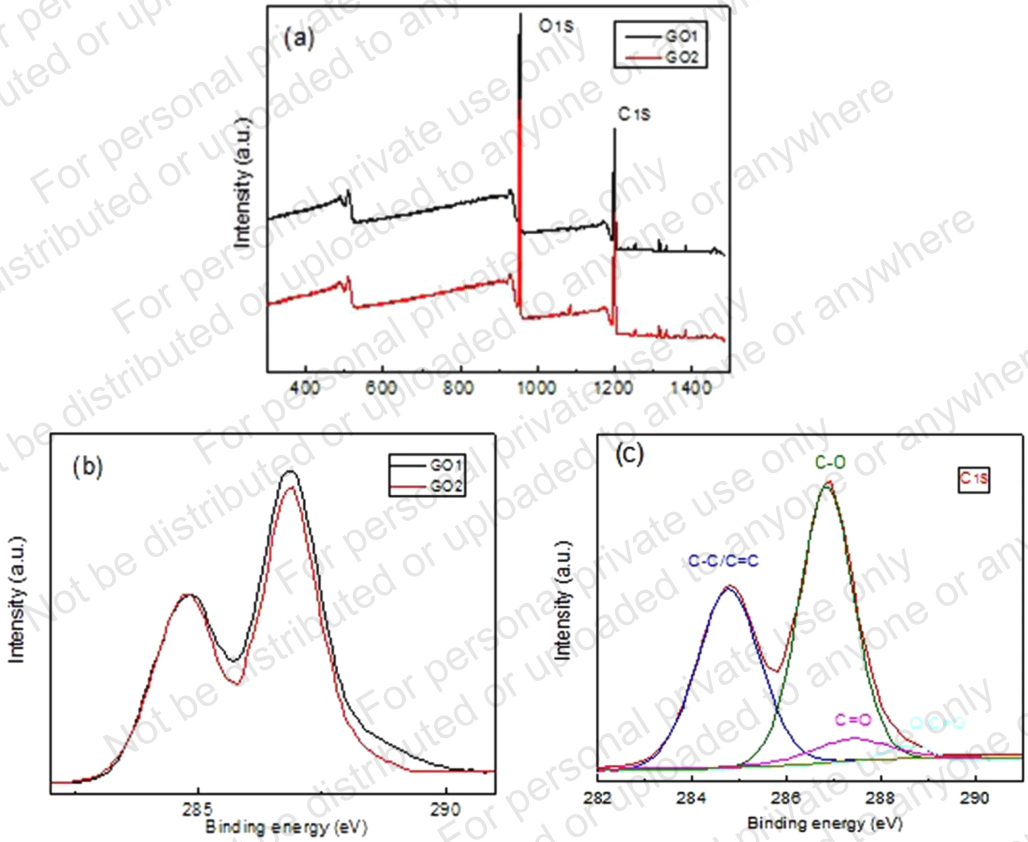

Fig. (11). The XPS of GO samples showing **(a)** GO1 and GO2, **(b)** C1s of GO1 and GO2 normalized to C=C peak, **(c)** deconvoluted C1s of GO2. Reused with permission from ref [98]. under Creative Commons CC BY license.

Ganguly *et al*. [100] reported *in situ* temperature-dependent XPS analysis of GO upon heat treatment process and observed that the unstable groups, such as the edge-plane COOH and C=O were stable and difficult to remove [100]. The C=O peak at 200 °C appears at ~ 288.3 eV, and the C-OH peak remains even at 1000 °C [100]. This peak indicates that thermally pyrolysis of the C-OH group is not

complete even at very high temperature and due to intercalating position of the C-OH group in the interlayer galleries, which is between intact conjugated regions [100, 101].

The C1s components in GO samples are a) carbon atoms of graphitic material with a peak at 284.5 eV, b) carbon atoms of alcohols (tertiary) and epoxides at 286. 5 eV, and c) the carboxylic acid groups at 289.2 eV [93]. The signal of ketones is placed between 287.7 to 288.1 eV [93, 102]. However, the interval has been placed either into 286.5 to 287.5 eV (along with alcohol and epoxides) or 288.5–289.2 eV interval (along with carboxyl groups) [93]. The deconvoluting integral C1s spectra are reported in various ways, for instance, the spectral deconvolutions of C-O-C and C-OH peaks [93, 100, 103]. Nonetheless, the overall oxidation level of GO or rGO can be interpreted with confidence using XPS analysis [93].

Siokuo *et al*. [104] have adopted two different methodologies to grow atomically clean graphene layers on Cu substrates. One of the methodologies is the stepwise annealing up to a temperature of 750 ºC and the second process is the treatment using mild Ar^+ sputtering under UHV conditions [104]. The XPS spectra of C1s of single-layer graphene grown on Cu foil treated at different temperatures. The XPS analysis in this report [104] has a much stronger C-OH peak. The sample of pristine graphene has peaks at 284.5 eV of C=C bonds, 285.6 eV for sp^3 hybridized carbon and peaks for C–OH and O–C–O bonds at 286.7 eV and 288.3 eV, respectively. The intensity of peaks corresponding to O-C-O and C-OH bonds indicates the presence of amorphous and oxidized carbon contamination [92, 104].

Rabchinksii *et al*. [105] have fabricated aminated graphene by simultaneous reduction and amination of GO under mild conditions. This facile and scalable fabrication involves treating GO with hydrobromic acid and ammonia solution [105]. The aminated graphene bears a low content of various other nitrogen species (graphitic N and pyridines), and this was confirmed from XAS (X-ray absorption studies) and XPS analysis [105]. The XPS spectra of brominated GO, rGO-Br, aminated graphene oxide, rGO-Am and precursor GO are shown in Fig. (**12**) [105].

The C1s peak in GO appears at ~284.7 eV, and O1s peaks in GO appear at ~ 532.6 eV, demonstrating no impurities were present [105]. The presence of bromine in the brominated GO demonstrates the Br3p doublet peaks at ~ 182eV and 189 eV, for the Br3d band at ~ 69 eV was confirmed from XPS analysis [105]. The absence of these Br-related peaks and the presence of N1s peak at ~ 400 eV indicated the amination of rGO-Br; furthermore, the incorporation of

nitrogen functionalities had a concentration of about 5.5 at. % [105]. The peaks appearing at 285.1 eV, 284.7 eV, and 283.9 eV correspond to sp^2 C=C domains, carbon atoms having bond distortion due to the presence of functional groups at the neighbouring C-C atoms vacancy defects in graphene lattice [105].

(a) XPS survey spectra of the pristine GO, brominated rGO-Br and rGO-Am. **(b)** High-resolution XPS spectrum of rGO-Br (Br3d). **(c)** N1s XPS (high-resolution) of rGO-Am. **(d)** C1s spectra (high-resolution) of the initial GO and modified rGOs. For clarity, C1s spectrum and their fits are vertically offset from the fitting components [105]. Reused from ref [105]. under Creative Commons CC BY license.

Besides XPS, extended X-ray absorption fine structure (EXAFS) is also utilized as a powerful technique for structural characterization (bond length and coordination number) of GBMs [106 - 108]. The local structure around the element of interest can be evaluated using EXAFS; thus, metal coordination or metal absorption can be studied to evaluate the potential applications [106 - 108]. GBMs are employed for a number of applications related to environmental remediation, catalysis, energy, water desalination, *etc* [106 - 108]. For contamination absorption (*e.g.*, heavy metal) or the use of GBMs as a catalyst, the local structure around an element of interest can be studied using EXAFS [106 - 108].

The strength of X-ray absorbed by material as a function of energy provided by the X-ray radiations is measured [108]. The absorption of heavy metals [Pb(II), Cd(II), and U(VI)] using multi-layered graphene oxide (MLGO) was studied recently using XAFS [107]. Inner-sphere and the outer-sphere mechanisms were concluded to be the crucial mechanisms of heavy metal absorption onto MLGO [107]. EXAFS and Near-edge X-ray absorption fine-structure have also been used to study the structure of GBMs [107 - 110].

6. THERMOGRAVIMETRIC ANALYSIS (TGA)

Various techniques discussed above are used for the characterization of graphene or graphene-based materials, typically probing properties only of a small sample area. These localized analytical techniques can also characterize the industrially produced graphene materials; however, it has been shown that graphene material produced on a large scale may not be graphene [111, 112] but instead can be a few layers of graphene (FLG) having non-exfoliated graphitic materials or impurities [111, 112]. The FLG, as described by ISO (International Organization for Standardization) [113], is a 2-D material with 3-10 stacked graphene layers [111]. Recently, the TGA analysis of GBMs has been performed to demonstrate the analytical application of TGA for characterization by recording and analyzing TGA/DTA thermograms [111, 112]. TGA, a thermoanalytical technique, measures the mass change with respect to temperature rise. The mass change can occur due to oxidation, decomposition, moisture loss, or loss of volatiles [114]. In this regard, the TGA-DTG of materials, such as graphite, FLG, GO, and rGO was recorded, and the decomposition with temperature was analyzed in terms of various characteristic parameters, such as DTG (derivative thermogravimetry) peak-range and -shape, maximum mass decomposition rate (T_{max}) and thermal stability. These parameters closely related to intrinsic physical and chemical structures were studied to identify graphene-based materials [111, 112] undoubtedly. The authors [111, 112] designed a hypothesis of using TGA as an analytical method, and this hypothesis was verified by recording TGA/DTA of controlled, verified samples of FLG, GO and rGO. These samples were also characterized by XPS, SEM, TEM, particle size distribution (PSD) and XRD. The TGA/DTA characteristics of these samples were grouped into analytical parameters. These parameters (DTG peak range and shape, T_{max} and thermal stability) were further used for the identification of GBMs [111, 112].

The TGA-DTA signatures of GBMs involved the division of thermographs into three distinct temperature regions [111]. Region I (RGI): water evaporation region (temperature, $T < 100$ ° C); region II (RGII): decomposition of oxygen-bearing groups (T =100°-360°) and region III (RGIII): carbon combustion (T = 360°-

1000°). Three DTG peaks were reported [111] for GO samples in each region, with T_{max} values of 221.2 ± 1.2 °C in region II and 555.5 ± 5.0 °C in region III. For rGO, only one DTG peak with a different position and T_{max} was observed in region III. The T_{max} values in RIII for rGO, FLG, and graphite were observed at 536.5 ± 5.0 °C, 703.9 ± 0.5 °C, and 871.3 ± 0.1 °C, respectively [111, 112]. It was reported that the T_{max} values are highly distinct for the studied GBMs [111, 112]. The T_{max} values were different for these GBMs, and the values vary with their chemical structures and carbon structures. The highest T_{max} was reported for graphite, followed by FLG, rGO and GO with lower values, resulting in significant differences in carbon decomposition temperatures. The graphite decomposes at higher temperatures than FLG, rGO and GO. Graphite, which contains many stacked graphene layers, is more thermodynamically stable owing to additional van der Waals interactions within the layers [111]. Thus, graphite requires higher temperature treatment for its decomposition due to the strength provided due to coexisting covalent bonding and the van der Waals interactions. The three regions in thermographs of graphite, graphene, and GO are shown in Fig. (**13**) [112].

Fig. (13). The representative TGA-DTA thermographs along with T_{max} values of graphene, graphite, and GO [112].

The oxidation of graphite sp^2 hybridized carbon atoms forming GO leads to the conversion of the majority of sp^2 hybridized C-atoms to non-graphitic sp^3 hybridized carbon atoms. Additionally, the defects' density also increases due to extensive oxidation during the said conversion. The presence of defects and oxygenated groups leads to a reduction of GO strength, and GO decomposes at a lower temperature [111, 112]. The reduced-GO shows similar behavior in RGIII to that of GO, indicating that the sp^3 carbon framework has not recovered to the graphitic structure. The distinguished TGA/DTA behavior of GO and rGO was reported in RGII; here, no DTG peak was observed as most of the oxygen functional groups present in GO were removed during the reduction process when rGO was formed. It is worth mentioning that the authors have compared the results with available literature data and the data collected from more than

hundreds of samples from other laboratories [106]. Thus, DTG peaks and values of T_{max} can be used to distinguish and identify graphite, FLG, GO and rGO. For qualitative analysis, several samples (commercially available as well as synthesized in lab) were analyzed using TGA/DTA, and the results were compared with verified GBM samples. The TGA/DTA results used for quantitative and qualitative analysis of GBMs were also in good agreement with other commonly used characterization techniques such as Raman spectroscopy, TEM, AFM, XRD, SEM and XPS [111, 112].

Wang *et al*. [115] facilely fabricated and then characterized graphene nanosheets. The synthesis was performed by oxidation, ultrasonic exfoliation, and chemical reduction. The nanosheets were characterized using XRD, HRTEM, TEM, and selected area electron diffraction (SAED). The TGA analysis of graphene nanosheets, GO, and pristine graphite powders was also performed in dry air to characterize and study the thermal behavior [115]. GO shows two-step mass loss with the rise of temperatures, one at 200 ºC due to removing oxygenated groups and the other at a higher temperature of 500 ºC because of carbon oxidation [115]. The pristine graphite losses mass at a much higher temperature of 650 ºC, which was combustion to carbon dioxide. The mass loss in the case of less stable graphene nanosheet (as compared to graphite bulk powder) was reported at 250 ºC. Similarly, Shtein *et al*. [116] have also characterized graphene-nanoplatelets by thermogravimetry in addition to Raman spectroscopy, electron microscopy, AFM and XPS analysis.

Recently, GO and rGO were used as fillers for the synthesis of polymer composite with poly(vinyl alcohol) as the polymer matrix [117]. The composite was studied for IR shielding applications. The filler GO and rGO were characterized along with TGA analysis. The TGA/DTA was performed to check the thermal stability of GBMs [117]. Three peaks were observed for GO, the first peak corresponding to water loss, the second peak at 200 ºC due to the decomposition of GO as oxygen groups were removed and at 500 ºC, beyond which the GO was completely decomposed. The GO was reduced chemically (using citric acid or hydrazine) and thermally (at 200 ºC or 1000 ºC) GO, and the rGO was again analyzed by TGA/DTA. The analysis indicated that a strong reducing agent or higher temperature treatment was able to lower the oxygen content in rGO significantly [117], as supported by decomposition trends in thermographs. Thus TGA/DTA analysis has been used for the characterization of GBMs. The degree of oxidation during GO formation can also be evaluated facilely using TGA [106]. In oxidized graphene samples, the mass loss of the functional groups can be studied quantitatively by TGA, and when combined with mass spectra or FTIR, more accurate information can be obtained [106, 111, 112].

7. CONCLUDING REMARKS

The affinity of hydrocarbons toward graphene leads to hydrocarbon contamination [53]. The hydrocarbons can come from vacuum grease, solvents, oil pumps *etc* [53]. This contamination is a challenge for the characterization of graphene by XPS analysis. Furthermore, oxygen-rich functionalities are liable to get reduced in the presence of X-ray beams, so this issue needs to be considered while recording XPS spectra [53, 93]. Additionally, the sample analysis is performed under a vacuum compared to the ambient atmosphere required by other techniques, such as Raman analysis [53, 93].

The characterization techniques in this chapter provided crucial information regarding atomic level as well as surface, chemical, and electronic properties of graphene-based materials. Optical microscopic techniques can make the visible distinction between graphene layer-by-layer or stacking. The information regarding 3D structural integration along with simultaneous vibrational and electronic properties can be evaluated. For practical application of GBMs, which depends upon controlling surface contamination, tuning surface properties, gram-scale fabrication process, and modulating electronic properties can be possible by targeted fabrication/modification approach. In this regard, the characterization of the material, both raw and processed (synthesized), is highly desirable. Thus, a brief discussion is made in this chapter regarding some of the important GBMs characterization techniques.

LIST OF ABBREVIATIONS

AC-TEM	Aberration-corrected transmission electron microscope
AFM	Atomic force microscope
ALD	Atomic layer deposition
BLG	Bilayer graphene
BZ	Brillouin zone
CNTs	Carbon nanotubes
CVD	Chemical vapor deposition
DOS	Density of states
DTG	Derivative thermogravimetry
FJH	Flash Joule heating
FT-IR	Fourier-transform infra-red spectroscopy
GBMs	Graphene-based materials
GO	Graphene oxide

Abstract: Carbon and its driven materials have been a foundation of living and non-living systems for centuries due to their amazing experimental expressions in light, temperature, pressure, and pH. Being light-weighted and electronically active with equal energy partitioning in its four orbitals ($2s^1 2p_x^1 2p_y^1 2p_z^1$), the C atoms have been at the core of natural sciences, providing valuable resources like high-grade wood, cotton, and many others. Thus, carbon-driven materials like diamond, graphite, and graphene ink have been attracting the attention of scientists, researchers, and industries. The chapter reviews recent chemical methodologies for the synthesis and structural investigation of graphene and its derivatives by various analytical techniques that provide information about basic knowledge to understand the role of graphene and graphene-based composites in various qualitative and quantitative applications. Here, several methods have been enlisted for the surface alteration of graphene oxide by a synthetic approach, such as ultrasound, a microwave-assisted synthesis that avoids the use of hazardous chemicals. Also, conventional methods have been discussed, including various types of reactions, such as nucleophilic, electrophilic, condensation, and cycloaddition. This review article highlights the key points to understanding the 2D carbon material for researchers and users to learn about the chemical modification of graphene at the initial stage. This write-up also discusses a brief explanation of various carbon nanomaterials that concern graphene and its oxide forms. We have explained the synthetic value of 2D carbon materials so that it covers a lot of the needs of researchers for synthetic aspects in graphene and allied fields of interest. Currently, such unique experiments are noted as milestones in the field of material synthesis for various applications. So, a review of chemically altered graphene materials reinforced with structural multi-functionalities is highly informative as a ready reckoner for needed information and understanding.

INTRODUCTION TO CARBON CHEMISTRY

Carbon is the fourth most abundant chemical element in the universe and the second most abundant in the human body by mass [1]. The atomic number of carbon is six and it belongs to the second period of the fourteenth group [IVA group] of the periodic table. A carbon atom has six electrons with $1s^2$, $2s^2$, and $2p^2$ electronic configurations, which infer tetravalency. Two inner shell electrons are spherically symmetric; out of which, 1s orbital is tightly close to the nucleus. The energy difference between 1st and 2nd shells is far from the Fermi energy levels, and remaining four valence electrons ($2s^2$, $2p^2$) have very similar energy to silicon. The energy difference between the 2s and 2p orbitals of carbon is relatively low compared to the bond enthalpy. The tetravalent nature of carbon and its distinctive catenation property can be accessible for hybridization, forming new compounds. Thus, 2s and 2p orbitals hybridize (Fig. **1a,b**). The catenation property of carbon results in stable allotropes of 0D, 1D, 2D, and 3D dimensionality compared to other elements [2].

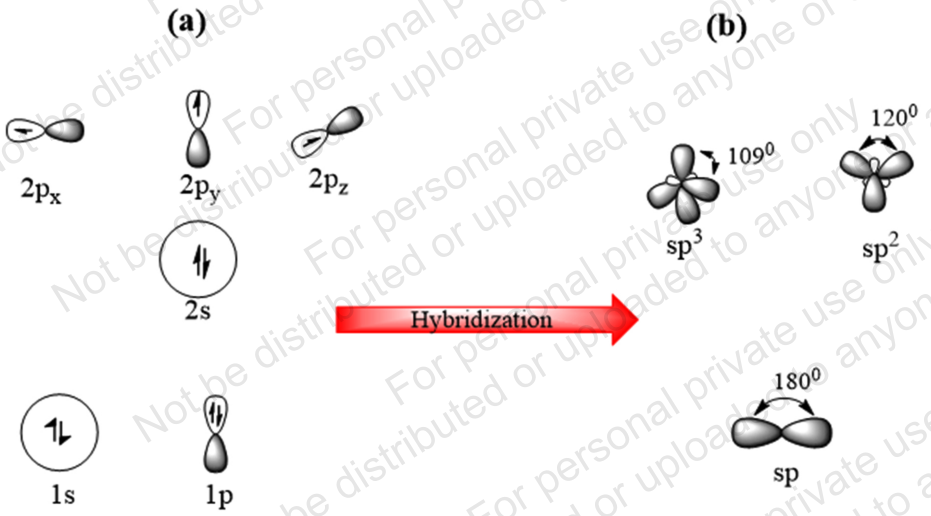

Fig. (1). (**a**) Diagram of atomic orbitals, and (**b**) hybrid orbitals of carbon.

POLYMORPHISM OF CARBON

Carbon has the ability to bind with various elements like H, Si according to optimal hybridization, supporting the synthesis of compounds with different

structural properties and applications. Therefore, newly synthesized compounds have different geometrical features, like sp hybridized carbon which is linear in nature, while sp^2 and sp^3 have trigonal planar and tetrahedral structures, respectively [2]. The one p and one s-orbital hybridize as sp while, two p and one s-orbital hybridize as sp^2 carbon, and remaining unhybridized orbitals participate in forming an additional π bond. Therefore, the tetrahedral lattice of the diamond (Greek 'adamant' meaning impossible to tame) belongs to sp^3-hybridized carbon atoms in terms of strong covalent bonding to itself [1, 2]. The wave function of four valence electrons ($2s^2$ and $2p^2$) of carbon, hybridize easily and it adds to the solid-state features of sp^2 hybridized graphite (Gt). The diamond and Gt are two natural allotropes of carbon. The diamond and Gt allotropes have been known since prehistoric times for their distinctive properties such as hardness, thermal conductivity, and lubrication behaviour [3, 4]. In the last few decades, the surprising discoveries of three artificial allotropes of carbon, *i.e.*, 0D fullerene, 1D carbon nanotube, and 2D graphene (Gr) have confirmed the efficiencies of carbon materials for their amazing applications [1 - 8] (Fig. **2a-e**).

Natural Allotropes

Diamond

Diamond is a sp^3 hybridized natural allotrope of carbon with structurally strong C-C covalent bonds [1, 2]. The crystal structure (Figs. **3a, b**) of the diamond is known for its excellent properties; such as high Young's modulus, hardness (hardest material with a supreme Mohs value of 10), chemical inertness, low electrical conductivity, high thermal conductivity (900–2,320 W/m/K), high X-ray, and high optical scattering ability of visible spectrum 1-1.5 eV [1, 9, 10].

Natural diamond, high-pressure synthetic diamond, low-pressure synthetic diamond, and metastable carbon or diamond-like carbon are the four types of diamonds known to date [8]. Natural diamonds are produced at a high temperature and pressure in volcanic eruptions. Moreover, English chemist H. Davy proved that the burning of diamonds produced only CO_2. Initially, in 1955, the first unquestioned high-pressure synthetic diamond was synthesized in the Institute for High-Pressure Physics of the Soviet Union, the U.S. and Sweden. It was commercialized for various industrial applications such as wear, abrasive, and tools. The preparation of low-pressure synthetic diamond is based on chemical vapour deposition (CVD). A diamond-like carbon is produced by a thin coating at low pressure [8]. The C-C strong covalent bonds in diamond are responsible for the thermal conductivity as well as its valuable applications in microelectronics, optoelectronics, and carbon fibre electronics. Diamond acts as an insulator at RT with a resistivity 10^2 Ω and a wide bandgap (~5.5 eV) [11, 12].

Where a, b, and c are primitive lattice vectors:

Fig. (3). (a) Crystal structure of diamond, and **(b)** fcc lattice with a set of primitive lattice vectors.

The direct lattice (linear combinations) for the diamond is stated to be face-centred cubic (fcc) (Fig. **3b**) with primitive lattice vectors a, b, and c. The dissimilarities of primitive lattice vectors shown in Figs. (**3a** and **b**) are given below:

$$a = (0, a/2, a/2),$$

$$b = (a/2, 0, a/2),$$

$$c = (a/2, a/2, 0),$$

where a, b, and c are the lengths of the edges of the smallest cube in the fcc lattice. The unit cube, or crystallographic unit cell, is the smallest cube of the direct lattice [10]. The CVD-synthesized diamonds have potential applications in

various fields such as electronics, optics, mechanics, thermals, chemicals, and others. The supreme hardness of a diamond is useful for cutting-edge applications. In chemical synthesis of nanodiamonds (NDs), the detonation process retains heterogeneous functional moieties such as carbonyl, alcohol, epoxy, ether, and unsaturated double bonds on ND surfaces. The surface functionalization of DNDs to produce highly unstable intermediates such as acyl and ester is accountable for amidation and esterification [12 - 14]. Thus, newly functionalized NDs have various applications in biomedical engineering, biophysics, electronics, optical devices, and mechanical studies. Recently, the NDs have been utilized as drug carriers due to their stable dispersibility subjected to drug and gene delivery and imaging systems [12 - 15].

Graphite

3D flakes of Gt are amorphous and crystalline in nature. The multi-layered planar hexagonal 2D sheets of Gr are stacked by weak Van der Waals forces. In each plane, the carbon atoms are arranged in such a way that each carbon atom is sp^2 hybridized along the hexagon lattice [16] (Fig. **4a,b**). The length of the hexagon lattice is 0.142 nm and the interplanar distance is 1 nm. Due to weak interactions between the sheets, the Gt is reported as the softest natural material (Mohs hardness of 1). Its electrons move over the sheets and, being a soft material, graphite is used as a lubricating agent in industries [1 - 5]. However, the reason for the interaction between the sheets is not entirely understood. Unlike diamond, the delocalized π-electron clouds over the sheets of Gt produce good electrical conductivity [17, 18]. Gt and graphite oxide (GtO) are used in the synthetic transformations as carbocatalysts to avoid hazardous organic reagents and solvents. The Gt acts as a carbocatalyst in microwave, conventional, and ultrasound-assisted synthesis, offering various synthetic transformations such as reduction of substituted nitro functionalities to their respective amines using hydrazine hydrate, cleavage of ethers followed by coupling with an acyl halide, Friedel-Crafts-type substitution, Diels-Alder reaction, cycloaddition reactions, and ene-cyclization. Also, GtO is used as a selective and highly efficient oxidant of thiols and sulphides [19 - 25]. Oxidation of Gt produces GtO which further facilitates ultrasound-assisted exfoliation into graphene oxide (GO) followed by surface functionalization [18, 26 - 31]. Birch reduction of Gt with lithium in liquid ammonia gives a highly reduced exfoliated product which is free from metal. The reduction is due to edge and interior hydrogenation [32]. Gt, GtO, reduced GtO and surface functionalized GO composites are found to be potentially applicable in electrical, optical, mechanical, energy storage devices, capacitors, and biological areas of research and industries [18, 27, 33, 34].

Synthetic Allotropes

Fullerene

Fullerene is a 0D synthetic allotrope of carbon with a face-centred cubic crystal lattice. The credit of fullerene's discovery goes to a group of scientists including Richard Smalley, Robert Curl, Harry Kroto, and Heath and O'Brien, at Rice University, Huston, who compared the structure of fullerene with the geodesic dome model of American architect Buckminster fuller. In 1996, Richard Smalley, Robert Curl, and Harry Kroto were awarded the Nobel Prize in Physics [35]. They proposed the icosahedron shape of the molecule possessing 32 faces, 60 apexes (carbon atoms) and 90 ribs within 12 pentagons and 20 hexagon rings to make a spheroid shape of the molecule. The point group symmetry of this molecule is I_h [36]. The chemical stability of the closed-hollow-cell of C_{60} is proved by a large energy gap between HOMO and LUMO [36 - 38]. The Van der Waals diameter of fullerene is 10.1 Å and the nucleus-to-nucleus diameter of C_{60} is 7.09 Å. The C-C bond length between two hexagons is 1.40 Å. It is considered as a double bond and slightly shorter than the C-C bond length of hexagon-pentagon *i.e.* 1.46 Å [36 - 38]. The functionalization of fullerene comprises exohedral and endohedral orientations, depending on the added substituents outside and trapped inside the cages. The chemistry of fullerene covers a wider range of chemical reactions like nucleophilic addition, electrophilic addition, electrocyclic reactions, radical addition, metal doping, and supramolecular complexation [39 - 57]. The exohedral modification of fullerene cages has been done by reacting with sulphur-containing group thiols, thioethers to facilitate the adsorption on the metal surfaces [39] and explored for their applications in various research areas and industries. C_{60} acts like a 2π electron-deficient dienophile and dipolarophile, hence enduring cycloaddition reactions such as [2+2], [3+2], and [4+2] on the 6, 6-ring junctions of the fullerene skeleton, either thermally or photochemically [40, 41]. The reactive divalent species, a carbene, has synthesized new derivatives and

enhanced the reactivity of fullerene [42]. In a one-pot reaction, a charged zwitterion intermediate with added nucleophiles with multiple functional groups is fitted onto the fullerene [43]. Fullerene has been named "radical sponge" due to its extraordinary reactivity towards radical species. Therefore, the highly reactive species are very attractive for functionalization [44, 45]. Although fullerene is insoluble in water, treatment with hydrogen peroxide converts it into a water-soluble polyhydroxy functionalized fullerene. Apposite functionalization of fullerene also makes the molecule soluble in water. Hence, water-soluble derivatives interact with DNA, protein, and living cells and find biomedical applications [46, 47]. There is aggregation of fullerenes into colloidal crystals due to fullerene-fullerene and fullerene-water driving forces in an aqueous or biological medium. Most of the photoactivity of nC_{60} is lost during the process, whereas aggregates of hydrophilic functionalized nC_{60} may or may not have reduced photoactivity, depending on the functional characteristics [47, 48]. Fullerene-based Friedel-Crafts arylation, alkylation, and acylation are multistep procedures for functionalization in synthetic chemistry [49]. The hydrogenation reaction is accomplished *via* the Birch reduction. The reaction of fullerene with hydrogen atoms makes hydrofullerenes, similar to the addition of H_2 at the C=C double bond, which results in the adduct of two C-H bonds [50]. The radical derivative of the fullerene is analysed by the most efficient analytical technique, *i.e.*, electron spin resonance (ESR) spectroscopy [51]. Fullerene and its alkali-doped composites such as M_3C_{60} (M is an alkali metal) [37, 52 - 54] and organic ferromagnets have been found as superconductors [54, 55]. The vast array of chemical reactivity promises a growth of various fullerene-based materials with their uses in polymer chemistry [56], biological applications [57, 58], catalysts [59, 60], organic electronics [61], photovoltaic [62], and thin-film transistors [63, 64].

Carbon Nanotube

In the year 1991, Sumio Iijima discovered the multi-walled carbon nanotube (MWCNT) [65], with multiple coaxial tubular units of single-walled carbon nanotube (SWCNT) rolled up by Van der Waals forces [66, 67]. MWCNTs are multi-stacked structures with unique properties [65 - 68]. SWCNT can be synthesized by various methods, such as chemical approach (Fig. **5**) [67], arc discharge [68], laser ablation [68], and CVD [69]. The principle of SWCNT synthesis implies that the hexagonal honeycomb carbon lattice of single-layer Gr gets rolled up into cylindrical helical hexagonal microtubules with a diameter range of 1-2 nm [70, 71]. CNT acts as a nanomechanical resonator in water to enhance the viscosity at low temperatures. It also applies to the mass measurement of biological molecules and various sensing applications due to their lightweight

nature, characteristic ultrahigh mechanical strength, and high surface activity [72, 73].

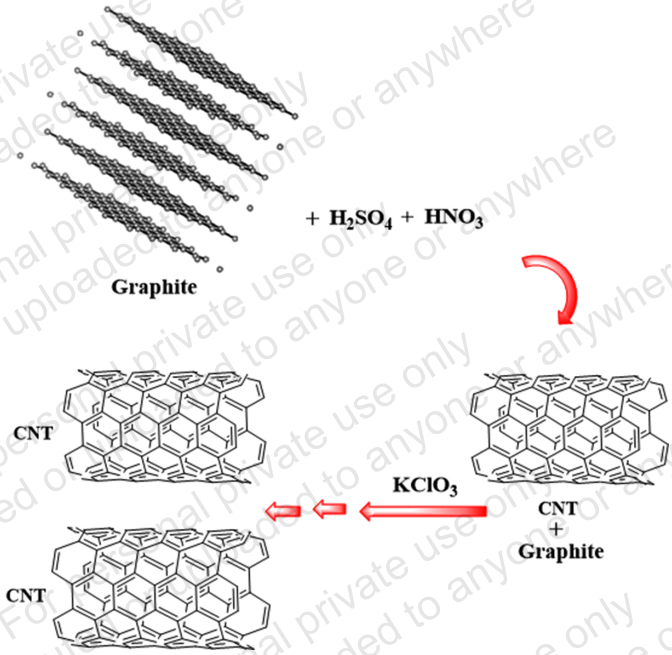

Fig. (5). Graphical representation of CNT synthesis by chemical approach.

The functionalization of CNT with organometallic compounds, metals, organic compounds, and biological molecules helps to manipulate the bandgap and heterojunction energetics [74 - 77]. Transformation of the assembled SWCNT into ultrathin long CNT fibrils has a great potential for applications as conductive wires and probe electrodes in industries [78]. The strength, small dimensions, and electronic, optical, and chemical properties of CNT-composite materials open a new direction for innovative applications, including [74 - 77, 79], energy storage electronic and semiconductor devices [80, 81], hydrogen storage media [82, 83], and high-performance hydrogen production devices [84].

Graphene

The Single-layered isolated sheet from Gt, is noted as Gr, which was first discovered through mechanical exfoliation using the “Scotch-tape” method from bulk Gt [85]. Epitaxial CVD [86] is also considered as a suitable method to grow Gr. The first experimental Gr was reported by Hanns-Peter Boehm in 1962, but it was not experimentally proven for so many years [87]. The comprehensive Gr study was started by Novoselov and Geim after getting the exfoliated single layer

Gr in 2004 and both were awarded the Nobel Prize in 2010 for ground-breakthrough research and its extraordinary properties. The atomic-level thin Gr possesses a 2D planar structure, having sp^2-hybridized carbon atoms with high charge mobility, mechanical properties (breaking strength ~40 N/m, Young's modulus~1.0 Tpa), thermal properties (at RT thermal conductivity~3000 $Wm^{-1}K^{-1}$), electronic, quantum hall effect, spin transport, and magnetism [85 - 94]. The electronic behaviour of materials is characterized in terms of the Fermi surface and controlled by external electric and magnetic fields [95 - 100]. However, due to the synergistic impact of nitrogen, N-doped Gr has become a promising material for various applications such as batteries, electronics, sensors, catalysis, and supercapacitors [96 - 100]. Furthermore, the ultrasound and microwave-assisted methods for surface modification of Gr have a wide range of applications [101 - 121]. In synthetic chemistry, unmodified Gt, GtO, and their derivatives catalyze redox reactions, alkylation, cycloaddition, and Friedel-Craft reactions [102 - 112]. The covalent functionalization of Gr could be demonstrated with the help of reactive intermediates such as radicals, nitrenes, carbenes, arynes, and nucleophilic substitutions like amidation or esterification [113 - 116]. The non-covalent approach for the surface modification of carbon-based materials comprises π-π stacking between the Gr surfaces and various biological molecules to synthesize bio-conjugates-proteins, enzyme-drug, DNA-protein complexes, and supra molecules-inorganic metallic complexes [119 - 121]. The impact of surface modification of Gr and graphene oxide (GO) demonstrates excellent electrical, mechanical, and optical properties, which could be further explored for the development of several biomedical devices, industrial metallic goods, conductors, energy storage devices, and transistors [120, 121]. The surface modification of Gr by using a robust chemical approach is the latest thrust area in the field of carbon nanotechnology to explore its several potential applications [102 - 116]. More-over, CNT and Gr are both carbon-based functional nanostructures, and they have different properties due to the diverse nature of their geometries which are planar in Gr and tubular in CNT.

REFINING OF GRAPHENE OXIDE

Initially, four methods were introduced in GtO synthesis. Each successive method has advancement in the simplicity, degree of oxidation, yields, and product quality. The impurities, *i.e.*, highly flammable salts and acids, are a major problem for GtO synthesis and purification, which makes it a dull procedure in GtO production. Multiple time washing, centrifugation, and filtration are important steps for the purification of GtO. Inorganic salts and acids are both quite water-soluble, but the purification of them is not easy since a gelatinous appearance of dispersed GtO is observed due to an increase in pH during washing

with water, which slows down the further purification, centrifugation, and especially filtration processes. Another best procedure for purification involves two-step washing with aqueous HCl and acetone to avoid gelation and accelerate the synthesis of purified GtO. Therefore, GtO is washed with an excess amount of HCl to remove salts and ions effectively, then acetone is used to eliminate the acid to make the pH neutral, which avoids gelation. The GtO is air-dried and allowed to disperse in acetone after 3 to 4 washes with HCl, followed by filtration and washing with more acetone, which removes residual HCl without gelation. In 1974, a similar purification process was described by Nikolaev *et al.* This purification method does not damage the various functionalities present over the surface. Thus, the solid GtO synthesis at a large scale can be achieved by filtration and vacuum drying. The salt content of GtO, washed with HCl and acetone 3 to 4 times, is measured. If the concentration is lower than 0.1 wt.%, then it goes unnoticed by Energy Dispersive X-Ray (EDX). Therefore, the purified GtO is quite stable against ignition. The GtO obtained by this method is utilized as a precursor in graphene synthesis [122].

SURFACE FUNCTIONALIZATION OF GRAPHENE OXIDE FOR STRENGTHENING CATALYTIC PERFORMANCES

Fabrication of Gr is cost-effective as compared to other carbon materials. Therefore, the researchers have focused their attention on exploring this material for various vital applications *via* surface modification of Gr, also known as the functionalization of Gr (f-Gr). Chemical functionalization of Gr avoids agglomeration and aids to sustain the intrinsic properties [122]. GtO is utilized as a starting material for the synthesis of Gr through chemical, thermal and photochemical reduction [123 - 127]. Oxidation of Gt helps to synthesize GtO, possessing various oxygenated functionalities over the surface, *i.e.*, hydroxyl, epoxide, diol, ketone, carboxyl, phenol, lactone and quinone [128 - 134]. The active functional groups expand the intercalative distance, to reduce interlayer Van der Waals forces. These help to improve the solubility and stability in water and organic solvents [135 - 139]. The presence of carbonyl and carboxyl groups at the edges of GtO sheets, makes it strongly hydrophilic and make stable dispersion in water using sound energy [135 - 137]. The different structures of GtO has been explained in the literature [128, 140]. But the stability of Gr is the necessity for chemical reduction of GtO due to rapid irreversible aggregation of the graphene sheet. Hence, the surface functionalization is linked with the composite materials which are synthesized by covalent and non-covalent functionalization [101].

Covalent Functionalization

Oxidation of the Gt produces various functionalities over the Gr surface. The numerous oxygenated functional groups on the Gr surface offer covalent modification. The aim of surface alteration of Gr in organic solvents is the stable dispersion to synthesize new composite materials for various applications. The principle of functionalization is to rehybridize one or more sp^2 carbon atoms into sp^3, which deals with the bandgap engineering by losing the conjugated electrons [2, 141]. The covalent modification of Gr can be achieved in four different ways [142 - 178].

1. Nucleophilic substitution reaction

2. Electrophilic substitution reaction

3. Condensation reaction

4. Addition reaction

Nucleophilic Substitution Reaction

The nucleophilic substitution reaction of GO is based on the accessibility of epoxy and carboxylic acid groups over the surface of dispersed GO in the aqueous and organic solvent phases. It has been reported that the epoxy and hydroxyl functional groups lie above and below, while the carboxyl group is at the edge of the carbon layer. Surface functionalization of GO with amine substituted organic compounds is simple at RT as a result of nucleophilic substitution and condensation reactions. Amide bond formation is one of the most vital reactions in organic chemistry because of its extensive applicability in the synthesis of modern biological and pharmaceutical compounds. The Lone pair electron of amine attacks the epoxy or electrophilic carbon center of the carboxyl group of GO. Since then, this method has been known for the large-scale production of functionalized (f) Gr. The acyclic and aromatic amines, amino acids, amine substituted biomolecules, ionic liquids, and small molecular weight polymeric compounds are functionalized with graphene oxide (f-GO) [101 - 104, 112 - 116, 120, 142 - 151]. Athanasios B. Bourlinos *et al.* explored the primary amines, possessing chemical formulas equivalent to $C_nH_{2n+1}NH_2$ (n = 2, 4, 8, 12, 18) of amino acids and nucleobases for surface modification of GtO and GO at RT [146 - 148]. Thus, the reaction condition depends upon the size of amine-substituted compounds. For a long-chain aliphatic amine, the reaction mixture is heated under reflux for several hours. The surface functionalization enhances the stability and dispersibility of f-GO in water and organic solvents. X-Ray Diffraction (XRD)

verified the functionalization of GtO at higher interlayer spacing (d-spacing) due to the amidation of GtO with amine substituted molecules [147]. The reaction between amino acids and GtO occurs in an alkaline solution due to the hydrophilicity of GtO. According to Bourlinos et al., the tilted orientation is more likely to occur due to its hydrophilicity [147]. Fan Zhang *et al.* for the first-time synthesized guanine-based covalently modified Gr. According to Fan Zhang, the amine group of guanines is covalently attached to the GOCl group, which is made *via* reacting COOH with $SOCl_2$. Thus, the synthesized compound is highly soluble in organic solvents with good potential in nanoelectronics [148]. The GO sheets were functionalized with the amine-end of the ionic liquid. The resulting composites were well dispersed in water, DMF, and DMSO without any addition of polymer or surfactant stabilizers [149].

Sang Hwa Shim *et al.* have shown a method to convert the hydrophilic groups of GO into alkyl or alkyl ether *via* a single-step bimolecular substitution reaction with alkyl bromide. Thus, the f-GO is dispersed as exfoliated sheets in various solvents, accomplished by covalent modification. The substitution of f-GO with solvophilic groups like polyethylene terephthalate (PET) on a small scale improves the electronic, mechanical tensile strength, and optical properties [152]. The dispersibility of GtO in organic solvents is potentially applicable to synthesizing polymeric-based composites [120, 153 - 157]. The GO surface was modified by an amidation reaction between carboxylic acid and amine substituted alkylamine [147], and esterification between carboxyl groups and alcohol polyvinyl alcohol [116]. Sungjin Park *et al.* produced a homogenous colloidal suspension of Gr sheets with the addition of polyallylamine to an aqueous suspension of GO sheet. Thus, this type of cross-linked sheet possesses outstanding mechanical stiffness and strength [153]. Wei-Hao Liao *et al.* have studied the fabrication of amine-substituted GO-polyimide composite film with high-performance capability using in-situ polymerization [154]. Zhiyuan Xu *et al.* made a polymeric composite of GO with 6-armed polyethylene glycol (PEG) by facile covalent amidation under mild conditions to make modified GO. GO-PEG was biocompatible in physiological solution and nontoxic to human lung cancer A-549 and human breast cancer MCF-7 cells. It was tested *via* cell feasibility examination [155]. Sunanda Roy *et al.* have established an effective chemical alteration with polyethylneimine (PEI) that converts into modified GO, which can extensively increase the overall strength of the nylon-12 composite. This method overcomes the drawbacks of developing advanced graphene-based polymer composites. Poor dispersibility is caused by factors such as restacking, weak interfacial bonding, and incompatibility with polymeric matrices, all of which suppress the potential action of Gr sheets [156]. GO esterification proceeds through converting the COOH of GO into an acyl chloride reacting with $SOCl_2$. Then, alcohol was substituted with organic molecules such as hydroxypropyl

cellulose or chitosan, which further covalently binds to the activated graphene oxide through esterification [116, 157].

Electrophilic Substitution Reaction

The synthesis of f-Gr or f-GO is based on an electrophilic substitution reaction in which a hydrogen atom is replaced by an electrophile [158 - 165]. The high electron density of the Gr induces more reactivity towards the strong electrophile. The substitution reaction was attained *via* grafting of aryldiazonium salt, Friedel–Crafts acylation and hydrogen–lithium exchange methods [158 - 165]. The diazonium salt of p-nitroaniline and 4-bromoaniline or para-nitro substituted aryl compounds have been embedded on the Gr surface [159 - 161]. M. Tour *et al.* have synthesized organic-soluble Gr by electrophilic substitution of aryldiazonium salt on the surfactant wrapped Gr surface [159, 160]. 4-bromoaniline was used for edge-selective functionalization [161]. Thus, chemically functionalized Gr is more dispersible than pristine Gr. The Friedel-Crafts acylation is still the only method for introducing the aryl ketone group onto the Gr surface [164]. A Friedel-Crafts acylation occurs through an intermediate of an acyl anion which is catalyzed in the presence of Lewis acid. Recently, T. Govindaraju *et al.* proposed the Friedel Crafts acylation of an exfoliated single-layer GO with ferrocene at RT. The reaction was achieved by making a solution of ferrocene in dichloromethane, which was adsorbed on acidic alumina by adding trifluoroacetic anhydride at RT [162].

Fang, Wang *et al.* have synthesized covalently f-GO using polystyrene through a three-step mechanism subsequently followed by oxidation of Gt, fixing of the atom through radical initiator and in-situ polymerization to the surface of a reduced Gr sheet [163]. In hydrogen-lithium exchange methods, the metal-substituted aromatic compounds (Ar-M) are more reactive than simple aromatic compounds (Ar-H). The metallated aromatic compounds are more reactive towards the electrophile for the formation of a covalent bond. It increases the length of the aromatic ring. Yan and co-workers proposed the functionalization of Gr using hydrogen-lithium exchange (deprotonation/carbometallation and subsequent electrophilic attack) method [165]. However, towards making a new solid catalyst with trimethylamine, it shows an electrophilic substitution reaction [164, 165]. The f-GO exhibited higher catalytic activity than sodium hydroxide for hydrolysis of ethyl acetate [164]. Jin Suk Chung *et al.* have proposed a new idea for the functionalization of Gr through a solvothermal process by using GO and NMP as precursors [166]. The solvothermal reduction and functionalization occur *via* generated free radicals from NMP and proceed similarly as in the functionalization of Gr by aryldiazonium salts [158 - 161, 166]. The restoration of electronic conjugation of C=C in Gr increases with reaction time. The f-Gr forms

a stable dispersion in organic solvents. Thus, the electrical conductivity of f-Gr is more efficient than pristine Gr [166].

Condensation Reaction

The condensation reaction is carried out by combining two compounds (functional groups) into a single molecule with a loss of energy. The condensation reaction of Gr takes place with isocyanate, diisocyanate, and amine through amide and carbamate ester linkages [164, 167 - 172]. Yanfei Xu *et al.* proposed a condensation reaction between 5-4-(aminophenyl)-10,15,20-triphenylporphyrin (TPP) and GO *via* an amide linkage. Modified GO was standardised and optimised for homogeneous dispersion in DMF. Consequently, the addition of the TPP-NH_2 has changed the electronic properties of GO, but no major effect is detected on the TPP-NH_2 part individually. The prevention of agglomeration is significant for processability and applications. Fluorescence quenching and energy loss occur as a result [167]. Zhuang Liu *et al.* have functionalized nanoscale graphene oxide (NGO) sheets (50 nm) by branching with biocompatible polyethylene glycol (PEG) to achieve higher aqueous solubility and stability in physiological solutions of serum. Thus, the unique features of Gr are revealed for drug delivery with water-insoluble aromatic drugs. The solubility of the drug decreases its efficacy. It revealed that PEGylated NGO (NGO-PEG) easily synthesizes complexes with water-insoluble drugs *via* noncovalent Van der Waals interaction. The hybrid NGO-PEG-SN38 composite displays excellent aqueous solubility and holds the high influence of free SN38 dissolved in organic solvents. The toxicity exceeds that of irinotecan (CPT-11, an FDA approved SN38 prodrug for colon cancer treatment) by 2-3 times [168]. Jianfeng Shen *et al.* functionalized GO nanosheets (GOS) with bovine serum albumin (BSA) *via* diimide-activated amidation. The GOS–BSA complex is highly water-soluble. BSA protein was used in this study; it contains 60 amino moieties in lysine and 26 arginine units in guanidino side chains. Infrared spectroscopy reveals the strong bands at 1690 and 1570 cm^{-1} for N-H stretching frequency of amide I and amide II, respectively. The thermogravimetric analysis (TGA) curves presented the lower thermal stability of f-GO compared to GO. AFM and Raman have demonstrated surface-functionalized GO. This method was used to synthesize the next generation of functionalized GO, with applicability for various applications [169].

Yuhua Xue *et al.* synthesized a polyhedral oligomeric silsesquioxane (POSS)-functionalized GO through an amide bond which is highly soluble in various organic solvents including tetrahydrofuran (THF), dichloromethane, chloroform, toluene, hexane, and acetone. Thus, POSS-Gr has developed super-hydrophobicity with a water/air contact angle of 157°. It could be utilized for the

construction of liquid marbles. The hybrid POSS-Gr was also used as nanofiller to raise the glass transition and decomposition temperature of polymers [170]. Sasha Stankovich *et al.* used several isocyanate compounds for surface functionalization of GO. Since the isocyanates functionalized graphene oxide (iGO) formed a stable dispersion in polar aprotic solvents, The functionalization of the hydroxyl and carboxyl groups in GO occurs through the formation of amides and carbamate esters, respectively. The efficiency of the functionalization is controlled by the isocyanates' reactivity or reaction time. iGO was not completely dispersed in the water. It was formed a colloidal dispersion in apolar aprotic solvents such as dimethyl sulfoxide (DMSO), hexamethylphosphoramide (HMPA), N-methyl pyrrolidone (NMP), and DMF using sonochemical technique. iGO material does not disperse in less polar solvents, such as THF, acetone, toluene, methylene chloride, or common polar solvents, such as ethanol and methanol. The stable brown dispersion of phenyl iGO in DMF contains no precipitate. Thus, the mechanism is very useful for the preparation of polymeric nanocomposites. Hence, isocyanate and diisocyanate are useful in GO modification through cross-linkage. The functionalization occurs through the formation of a covalent (amide linkage) bond between Ar-COCl (produced by the reaction of GO with $SOCl_2$) and the NH_2 functional group of octadecylamine (ODA) [171]. Mitra Yoonessi *et al.* proposed that the synthesized polyimide nanocomposite be shown to have superior mechanical properties and good compatibility with N-methyl-2-pyrrolidone. Since then, the thermal stability of polyimide nanocomposite has been enhanced by the addition of Gr [172].

Cycloaddition Reaction (Pericyclic Reaction)

The cycloaddition reaction differs from most of the organic reactions in which the formation of cation and anion is not essential. The electrons are moved cyclically, with the bond making and breaking spontaneously. The Cycloaddition reaction of Gr offers a new route for improving the bandgap, dispersibility, and solubility. There are four types of graphene cycloaddition reactions: 1,3 dipolar cycloaddition, [2+2] cycloaddition, Diels Alder reaction, and [2+1] cycloaddition reaction [101, 150, 164, 173 - 178]. The 1,3 dipolar cycloaddition reaction, also known as [3+2] cycloaddition, occurs *via* six electron cycloaddition between 1,3 dipolar and dipolarophile (graphene) to produce five-membered rings of azomethine ylides on Gr (functionalized Gr). Mildred Quintana *et al.* have prepared functionalized Gr by condensation of formaldehyde and protected a-amino acid, followed by a deprotection of the t-butyl carbamate group (Boc group). Meanwhile, functionalized Gr has developed a new method for making nanocomposite materials by using gold nanorods [164, 173]. The azomethine ylides are unstable in most of the cases of functionalization and are made by the decarboxylation of carbonyl species and an N-methylglycine (sarcosine). Other

than the edges, 1,3 dipolar reactions also occur at the C=C of the centre of the Gr sheet. Aijian Wang *et al.* proposed two possible routes for covalent functionalization of reduced GO (RGO) with porphyrin moieties by 1,3 dipolar reactions. The first method involves reacting RGO with sarcosine and 4-hydroxybenzaldehyde in dimethylformamide (DMF) at 145 °C, followed by nucleophilic substitution with w 5-[4-(2-bromoethoxy) phenyl]-10,15,2--triphenylporphyrin (TPP 1) in DMF and K_2CO_3 at 80 °C to derivatize RGO [174]. The second method involves making a formyl-inclosing porphyrin 5-[4--2-(4-formylphenoxy) ethyloxy) phenyl]-10,15,20-triphenylporphyrin (TPP 2) that is attached to the RGO through azomethine ylide. The attachment of RGO with porphyrin ensures efficient electron and energy transfer between them and improves the optical and electronic properties compared to the RGO and pristine Gr [174]. [2+2] cycloaddition comprises the four-electron cyclization process with Gr.

Zhong *et al.* have established a new efficient approach for the synthesis of chemically modified Gr by aryne cycloaddition under mild and neutral reaction conditions. Aryne modified Gr is highly thermally stable and well dispersed in water and organic solvents such as 1,2-dichlorobenzene, ethanol, and chloroform [175]. After the photochemical or thermal heat treatment, the Diels-Alder cycloaddition reaction or [4+2] cycloaddition has proceeded in a single step *via* six-membered ring formation. The reaction occurs between conjugated cis diene (electron-rich) and dienophile (electron-deficient). The reaction would take place favourably for dienophiles in the existence of an electron-withdrawing group. The interaction between the diene and dienophile is due to the good symmetrical overlapping between HOMO of the diene and LUMO of the dienophile. At high temperatures, Jeong-Min Seo and Jong-Beom Baek have developed the solvent-free mechanochemical approach for the Diels–Alder reaction of Gt (diene) with dienophile maleic anhydride (MA) or maleimide (MI) in a sealed glass bulb of argon at a high pressure of 160–220 °C. Dispersed in polar solvents, functionalized composites were used in a variety of applications [164, 176]. Hence, well-dispersed graphene function permits it to act as a more reactive dienophile or diene in Diels-Alder's reaction. Such a synthetic method has a high potential for reversible modification of Gr electronic properties *via* bandgap opening under mild conditions [177]. The unique method for the functionalization of Gr nanosheets is based on nitrene chemistry. This scheme is easy and efficient to introduce various functional groups (hydroxyl, amine, carboxyl, and bromine), long alkyl chains, and polymers, *e.g.*, poly (ethylene glycol, polystyrene) by covalent bond and stably stacked on the Gr surface to yield single-layer functionalized Gr from GO in a one-step reaction. Nitrenes are reactive intermediates that can be made from azide species through irradiation or thermolysis. Further, it can be tried for covalent functionalization with epitaxial

Gr and exfoliated Gt by [2+1] cycloaddition [178]. Thus, functionalized composites are confirmed with X-ray photoelectron spectroscopy (XPS), Atomic force microscopy (AFM), Scanning electron microscopy (SEM), EDX, XRD, Transmission electron microscopy (TEM), Brunauer–Emmett–Teller (BET), Fourier transform infrared spectroscopy (FTIR), Elemental analyzer (EA), and Solid-state nuclear magnetic resonance (SSNMR) spectroscopy techniques.

Noncovalent Functionalization

Noncovalent functionalization is an established technique for the surface modification of carbon-based nanomaterials. The noncovalent approach involves the hydrophobic Van der Waals interaction, which is prompted by an electrical interaction between two or more closely placed atoms, - interactions produced by the electronic cloud, and electrostatic force of interaction produced by electrically charged particles [101 - 121, 128, 140, 179 - 188]. Such functionalization requires the physical adsorption of suitable molecules on the Gr surface. Noncovalent functionalization is achieved by polymer wrapping, adsorption of surfactants [139] or small aromatic molecules, and interaction with sulfonated polyaniline [184], porphyrins [186], or biomolecules like proteins, enzyme-drug complexes, DNA-protein complexes, supramoleculars, and inorganic metallic complexes [117 - 119]. Surface modification of Gr and GO demonstrates excellent electrical, mechanical, and optical properties, which could be further explored for the development of several biomedical devices, industrial metallic goods, conductors, energy storage devices, and transistors [120, 121, 128, 140].

Surface modification of Gr using a robust chemical approach is the latest thrust area in the field of carbon nanotechnology to explore its several potential industrial applications [101 - 116]. The wet chemical dispersion of the Gr layer was prompted by multiple noncovalent functionalization in a suitable solvent, NMP. The first analysis was done on surfactants, *i.e.*, sodium cholate, sodium deoxycholate and dodecyl benzenesulfonate, for major alterations in material applications for enhancing efficiencies. In amphiphilic sodium dodecyl benzenesulfonate dispersion, the majority of the material uptake endorsements were observed. The utilisation of sodium deoxycholate leads by far to the uppermost level of individualization [139]. However, the selection of various matrices is an important factor for the incorporation and homogenous distribution of Gr to restore the electrical properties. Hence, adequate solubility of Gr-based materials in various solvents is a necessity for their future experimental applications [180, 181]. The stability of reduced Gr in various solvents is achieved *via* noncovalent functionalization of amine-terminated polymers [182]. The GO reduction is carried out in an aqueous medium by treating with hydrazine monohydrate and subsequently washing for the removal of agglomerated Gr

sheets and impurities. The amine-substituted polymer is solubilized in an organic solvent. The aqueous dispersion of RGO is added to the organic polymer solution [183, 184]. The electric biosensor was made by non-covalent functionalization of RGO with conducting polypyrrole, implant copolymer, *i.e.*, poly (styrenesulfonic acid-g-pyrrole) [183]. The sulfonated polyaniline functionalized Gr sheet enhanced the electrochemical activity and stability [184]. The dispersibility of Gr in water is increased by noncovalent functionalization of RGO with aromatic dyes like methylene blue [185] and porphyrin [186]. Its research is useful in the preparation of graphene-based electric conducting sheets [185, 186]. Gr has created a blue fluorescent material by combining coronene derivatives such as the tetrapotassium salt of coronene tetracarboxylic acid. Its liquid crystalline derivatives, ester and imide, exhibit high fluorescence emission in solution and solid phase [187]. Non-covalent functionalization of RGO with sulfanilic acid azocromotrop shows its applicability as a supercapacitor electrode material [188].

GRAPHENE OXIDE FUNCTIONALIZATION WITH AMINE SUBSTITUTED ORGANIC MOLECULES

Substituted organic compounds are highly attractive due to their importance in agrochemicals, pharmaceuticals, device manufacturing, supercapacitors, and nanomaterial synthesis. Amine substituted molecules may be either aromatic or nonaromatic, heterocyclic or non-heterocyclic, or aliphatic. The heterocyclic compounds are considered for their potency in various fields. Heterocyclic molecules are cyclic structures that bear one or two heteroatoms (other than carbon) in the ring. The ring size differs from three-membered onward and is most efficient up to eight members. The number of heterocyclic compounds is still increasing rapidly. Almost all natural drugs, such as papaverine, procaine, emetine, atropine, theophylline, morphine, reserpine, and codeine, are heterocyclic natural drugs. The most commonly known synthetic drugs such as chlorpromazine, antipyrine, metronidazole, methotrexate, captopril, diazepam, barbiturates, and azidothymidine are heterocyclic. Moreover, some pesticides, dyes, and herbicides are also heterocyclic [189 - 192]. The nucleobases of DNA and RNA are nitrogen-based heterocyclic compounds that are directly involved in the recording of genetic code for therapeutic applications [146]. The essential amino acids [115], natural pigments such as haemoglobin [193], chlorophyll [194] and some hormones have a heterocyclic core. These molecules have changed their potency after functionalization with Gr. The whole physiological process of life, such as the provision of energy, metabolism, respiration, hereditary transformation, and nerve impulse, is based on biochemical reactions in which many heterocyclic compounds are associated with vitamins, serotonin, enzymes, coenzymes, adenosine triphosphate [ATP], nucleic acids, and others. According to the literature survey, most of the natural products contain heterocyclic molecules,

revealing that nature itself likes heterocyclic compounds for equilibrating their life cycle because of their unique properties. The presence of heteroatoms in the heterocyclic compounds maintains the pH of many synthetic and biochemical reactions. The heterocyclic molecules undergo nucleophilic, electrophilic, condensation, and cycloaddition reactions. Such flexible reactivity is responsible for changing their electronic properties to enhance their efficiency for various applications.

ALTERNATIVES OF CONVENTIONAL METHODS FOR FUNCTIONALIZATION OF GRAPHENE OXIDE

The synthesis needs environmentally benign routes to maintain sustainability. Researchers are trying to develop a new chemical process for minimising the use of hazardous chemicals. The chemist is constantly looking for greener alternatives to traditional synthetic methods. Ultrasound-energy and microwave-irradiation are two of the thrust areas for achieving this goal. To explore new efficient and eco-friendly alternatives for chemical reactions to minimise the waste product by avoiding or reducing the use of conventional volatile organic solvents. Thus, several approaches have been reported, such as reaction under solvent-free (dry media) conditions, by the use of solid-supported reagents, mechanochemical mixing (grinding), and alternative activation and heating methods that utilize microwave and ultrasonic irradiation for synthesis. Therefore, to avoid overheating problems, the sonochemical approach is utilized for the synthesis of surface modified Gr-based nanomaterials [195 - 200].

Ultrasound-Assisted Functionalization: A Sustainable Technology

Ultrasound refers to sound waves (>20 kHz) higher than the upper limit of human hearing (16-18 kHz). The ultrasound frequency is generally kHz) higher than the upper limit of human hearing (16-18 kHz). The ultrasound frequency is generally considered to be between 20 and 100 MHz. The laboratory sonicator for performing chemical reactions generally has a frequency of 20 to 100 kHz, while the higher frequency of ultrasound waves is used in medical applications. The principle of ultrasound waves is based on the generation of acoustic cavitation, which favours a chemical reaction between 20 and 40 kHz. Higher ultrasound frequencies of 5 MHz and above do not produce cavitation, and this frequency range is used in medical imaging. The ultrasound waves are generated by the ultrasonic transducer, which converts the electrical and mechanical energy into sound energy.

The electromechanical transducer is made of quartz and is usually based on the piezoelectric effect. Applying equal and opposite electrical charges to the opposite faces of quartz tends to cause simultaneous expansion and contraction. The

speedily reversed charges put up a vibration that produces ultrasonic waves, *i.e.*, a piezoelectric effect. Recently, the piezoelectric transducer of ultrasonic equipment is made of ceramic impregnated barium titanate that transforms 95% of electrical energy into ultrasound energy [195, 196]. The proliferation of sound waves, with a continuous succession of compression and refraction, goes through the liquid medium, which permits the molecules to oscillate about their mean. Hence, the average distance between molecules decreases and increases simultaneously. In the refraction cycle, the average distance and attractive forces between the molecules in the liquid medium may be overwhelmed, causing the formation of bubbles. The bubbles continuously rise within a few cycles by taking some vapours or gases from the liquid medium to gain an equilibrium size which matches the frequency of bubbles to the resonance of applied ultrasound frequency. Therefore, the acoustic field experienced by the bubbles is not stable because of the interference of other bubbles forming and resonating around them. However, the internal forces are too high to confirm the violent collapsing of bubbles, producing a very high confined temperature of nearly 5000 K and a pressure of over 1000 bar. High temperatures and pressure can be involved in chemical reactions.

The term "sonochemistry" is used to explain the effect of sound energy through bond oscillation on chemical reactivity. Among several theories, the 'hot-spot' is the most acceptable for describing sonochemical reactions. It explains the release of energy through cavitation. A cavitation bubble acts as a localised microreactor in an aqueous system, generating thousands of kelvins of temperature and high pressure. The driving force for a chemical reaction under the influence of ultrasonic waves is driven by cavitation bubbles [197]. The broad applications of sonochemistry in synthesis have attracted the attention of many researchers. Interest has spread beyond academic laboratories into the industry and chemical engineering. Various ultrasound-assisted organic reactions, exfoliation of GtO [198] and nanomaterial synthesis, have been conducted in aqueous as well as in non-aqueous media and homogenous liquid mixtures. As a result, the wonderful properties of ultrasonic-irradiation have been highlighted for successful application in organic transformations.

Microwave-Assisted Functionalization: A Green Chemical Transformations

Microwave-assisted heating with a Bunsen burner is a 21st-century asset for its use in the synthesis of organic, nanomaterials, polymers, and inorganic materials. It is the homogeneous heating process that speeds up the reaction rate compared to conventional methods. The confined zone is electromagnetic radiation range of size 1 cm to 1 m, frequency 30 GHz to 300 MHz, and photonic energy 1.24 meV to 1.24 eV. The transition between infrared irradiation and radio frequency is

referred to as microwave irradiation [199, 200]. The mechanism of microwave irradiation is the interaction of electromagnetic radiation with dipolar molecules. Hence, the dipole moment directs it to become aligned and change its orientation due to electric field oscillations. Speedily reoriented molecules produce homogenous internal heating to proceed with the chemical reactions. Therefore, the choice of solvent is important for the microwave-assisted synthesis to consider a dipole moment [199, 200]. Surface modification of GO occurs in terms of an amide bond between the carboxyl group of GO and the amine group of chitosan, subsequently followed by reduction with hydrazine monohydrate. Thus, the dispersibility, aqueous solubility, and biocompatibility were enhanced by the grafting of chitosan on the GO sheet [201]. Therefore, a microwave is more valuable to get a quantifiable yield with more precision than conventional heating. The researchers are attempting to advance nanomaterial design and synthesis by monitoring all of these parameters such as temperature, pressure, temperature ramp, and polar solvent selection [199 - 201].

CHEMICAL REDUCTION OF GRAPHENE OXIDE

Most of the research work has been published for the functionalization of Gr using chemical, electrochemical, sonochemical, and microwave methods. GO functionalization has been done through the reduction of epoxy, carboxylic and ketone groups using reducing agents [124, 125]. The most commonly used reducing reagents are hydrazine monohydrate [126], sodium borohydride and their substituted derivatives [202, 203], lithium aluminium hydride [204], alkaline solution (KOH, NaOH) [205], metal iodides [123], hydrogen iodide [206], aluminium foil [207], alcohol [208], thiourea dioxide [209], p-phenylenediamine [210], L-ascorbic acid [211], nascent hydrogen [212], iron/hydrochloric acid [213], bacterial respiration [214] and pyrrole ring [215]. These chemicals are hazardous to the environment and living organisms. Hydrazine monohydrate, sodium borohydride, and lithium aluminium hydride are sensitive and explosive chemicals to moisture. The alkaline solution and organic solvents unbalance the whole aquatic system. Therefore, precautions are needed for Gr synthesis using bulk amounts of a strong reducing reagent. The alternative methods, *i.e.* metal/HCl-based reduction, such as Fe/HCl, are secure compared to explosive chemicals . But still, some problems exist due to the presence of an impurity in the reduced Gr. Recently, an acetic acid and HCl-based alternative method has been proposed, which is comparable to the reduction by hydrazine monohydrate. The elemental analysis of reduced Gr revealed a high C:O ratio vis-à-vis a loss of oxygen (reduction), high conductivity (4600 Sm^{-1}), and specific capacitance (35 Fg^{-1}) due to the attainment of unsaturation [208]. Green approaches such as microwave, ultrasound, and solvent-assisted, flash, thermal, and photochemical-based GO reduction have piqued the interest of researchers for large-scale Gr

production. Considering the literature review, the recent progress in Gr research is the enzymatic reduction of GO on a priority basis. For example, Martin Pumera *et al.* have proposed GO reduction by thiourea dioxide [209]. Aravind Dasari *et al.* have reported the dopamine-induced reduction and subsequently functionalization of the GO sheet [210]. Jingyan Zhang and Shouwu Guo *et al.* found the GO reduction using L-ascorbic acid [211], which is very close to that of hydrazine monohydrate [126]. James M. Tour *et al.* have shown bacterial respiration for GO reduction [214].

GRAPHENE-BASED MATERIALS TOWARDS VARIOUS CATALYTIC PERFORMANCES

The single-atom thick, 2D carbon hexagon network of Gr and its derivatives have remarkable applications in the fields of biomedicals [146, 148, 168, 216 - 225], nanoelectronics [226 - 230], energy storage devices [231 - 233] and organic synthesis [21, 110]. The magic material of the 21st century shows good mechanical [234, 235], optical [236 - 239], sensing [98, 121, 240 - 245] and adsorption [179, 246 - 255] properties. The amphiphilic nature of GO is seen from edge to centre in the dispersion of hydrophilic to hydrophobic domains. Therefore, GO acts as a surfactant and sticks to interfaces and lower interfacial energy sites [249]. The use of pure Gr is challenging due to its agglomeration and processing difficulties. So, the modification of Gr has attracted broad research interest. The grafting of polymers with GO increases the biocompatibility and stability in the cellular medium, and it is used as a nanocarrier for hydrophilic and hydrophobic drugs [220, 246]. Also, the GO functionalization with enzymes enhanced its thermostability, which has been extensively used in biotechnological applications to stabilise heat-sensitive enzymes [247]. Recently, the surface modification of GO has been utilized to make nanofiltration membranes for desalination purposes [248]. Still, there is not much research done to search for graphene in biological systems, despite much exertion in the area of CNT for *in vitro* and *in vivo* biological uses. f-GO has biocompatibility with organic molecules such as nucleobases [146, 148] to increase the high aqueous solubility and stability. A new hybrid nanomaterial was established as an exhibiting enzyme for *in vitro* analysis and therapeutic cure of cancer cells [168, 219]. Gr-based composites show a positive impact when imparting antimicrobial [222, 223] and antibacterial [224, 225] properties.

Arghya Paul *et al.* have discovered an injectable and biocompatible hydrogel of polyethylenimine (PEI) functionalized GO to easily deliver vascular endothelial growth factor-165 (VEGF) pro-angiogenic gene for myocardial therapy [221]. Self-assembled 3D Gr or functionalized Gr-based conducting nanostructures are suitable for designing flexible, thermally and electrically stable electronics [226 -

229], supercapacitors [227, 228, 230], energy storage devices [231, 232] and solar energy conversion schemes [233]. Gr-based nanomaterials are appropriate as highly efficient complexes with good mechanical properties such as high strength and modulus, which are prepared by adding a few numbers of fillers [234, 235]. Gr and Gr-based composites have sparked interest in optoelectronic applications such as photodetection [236], the synthesis of low-cost optical photovoltaic devices [237], and fluorescent nanocomposites [238, 239]. The most important application of f-Gr is to act as a sensor to diagnose the disease, which depends upon the large surface area of Gr. f-Gr can be sensitive to a particular disease. The dispersed f-Gr interacts with the biomolecules in the matrix. The more effective nanocomposites of GO are allowed to bond with single-stranded DNA, subsequently added by fluorescent molecules [98, 121, 240 - 245]. Tetiana Kurkina *et al*. established an f-GO-based device as an electrical biosensor for the immunodetection of amyloid-beta peptide [244]. Also, f-GO-based sensors have been developed for humidity and temperature sensing due to their suitable features such as flexibility, transparency, and bulk-scale production [245]. The porous nature of Gr and its derivatives is utilized as an adsorbent for hazardous chemicals, elements, and gases for environmental remediation. Gr-based composites decontaminate naphthalene and its derivatives [179], bisphenol A [250], toxic Cr (VI) [251], copper (II) [252], carbon dioxide [253] and mercury [254] from the ecosystem. The catalytic properties of unmodified Gt are found to be utilized for alkylation [21] and Friedel–Crafts acylation of aromatic compounds [20] to avoid the use of hazardous solvents and reagents. The fluorinated Gr acts as an electrophile, which substitutes amine and alcohol nucleophiles *via* covalent bond formation [255]. The excellent properties of Gr and its derivatives in several research inventions have given fruitful solutions. The synthesis of Gr-based composites by a robust chemical approach is a new and recent thrust area. The covalently modified Gr-based materials are further confirmed in the product with detailed analysis and electrical as well as photochemical applications [256, 257]. Hence The robust chemical approach for the surface functionalization of GO is suitable for synthesizing nanocomposites for biomedical applications [258 - 260].

Biomedical Catalysis

Gr-based modified materials have been extensively studied and reported for biomedical research like cell viability, cancer therapy, tissue implantation, antibacterial activities, antioxidant behaviour and as drug carriers due to their improved solvent processabilities. Furthermore, in the literature review, alginate-based functionalized GO has been selectively obstructed in the MDA-MB-231 cell line adhesion efficiency (human breast cancer cells) while promoting adhesion towards healthy murine fibroblasts (3T3) and human osteosarcoma

(HOS) [261]. There is variation in the adhesion efficiency towards the cancer cell MDA-MB-231. HOS is not similar to healthy cell 3T3 due to tumour cell specificity, but it is driven by topographical signals originated by alginate-GO based substrate. The use of various antibiotic medicines causes resistance against the pathogens, which needs to be modified with GO that endorses the stability with agglomeration reduction. So, the materials are used as drug carriers and antibacterial agents too [262 - 264]. The optimised nanosized GO function-alization with two derivatives, *i.e.*, polyethylene glycol and polyethyleneimine, is a new method for developing a si-RNA (si = small interfering) carrier-based delivery system. It improves the osseointegration implantation, which has been confirmed by cellular cytocompatibility investigation [265]. The modulation of the Gr surface as well as its functionalization have developed various functionalities like hydroxyl groups with surfaces' defects, which show excellent cytocompatibility with better mechanical strength. These facilitate cell differentiation and regeneration in the tissue engineering field [266 - 269]. The combination of highly electrically conductive Gr and titanium dioxide facilitates the separation of electrons and holes in the TiO_2 energy band and prevents recombination when ultrasound is applied. Thus, the TiO_2-graphene-based material is used as a nanosonosensitizer for therapeutic effects against tumours [270]. Therefore, biomedical science is essentially required for chemical modification of graphene to develop a new cost-effective artificial cytocompatible tissue that can be used as an alternative.

Photoluminescent Catalysis

The zero-bandgap has less applicability in optics. So, the oxidation of Gr opens the zero bandgap after generating various oxygen functionalities such as hydroxyl, carbonyl, carboxyl, and aldehyde to focus on the optical properties [271 - 277]. The photoluminescence (PL) of GO is seen in the visible or ultraviolet region, which is more intense than Gr. Two PL bands, one in blue and another in the red region (500-600 nm), are seen. The PL band of the GO is not yet simplified like organic molecules due to the presence of various electronic domains and uncertain functionality on the GO surface. The origin of PL bands is still being debated. The blue band has been observed due to the the π-π* transition of sp^2 electronic domains at the C-O sp^3 surface [277], while it is also claimed that π-π* transition has observed the broad long-wavelength (LW) band [278]. The broadband due to defects has caused a variation in the sp^2 domains' bandgap. The pH-dependent tunable PL bands of the GO resemble those of the polycyclic aromatic compound in a basic medium because the carboxylic functionalities are coupled with their neighbouring atoms of Gr. The blue band is intense at pH>8 and allocated for the optical-electronic transition from GO−COO* to GO−COO−. Hence, the LW band has developed an important factor at pH 8. It is ascribed to the LW band for an

optical-electronic transition from (GOCOOH)* to (GOCOOH) as an excited carboxyl group protonated into carboxylic acid. Further, the study concludes that the protonation and deprotonation of carboxyl and hydroxyl functionalities of GO were accountable for the dissimilar PL strength with pH of solutions [278, 279]. The COOH and OH are accountable for the blue and broadening the LW band [280, 281]. According to the theory of the red-edge effect, the performance of the blue PL band depends on the excitation wavelength. The red-edge-effect also explains that the solvation dynamics of GO in a polar medium decelerates miserably with the time scale of PL, resulting in a broadening of the red-shift of the PL band [282]. Hence, the surface-modified GO shows change in the PL bandgap as their corresponding PL peaks slightly differ compared to previously reported GO due to the difference in electronic domains at the GO surface. Therefore, the GO-based derived materials have attracted a lot of attention for PL and sensing applications due to their variable electronic structural insight and solubility in various solvents.

Magnetic Catalysis

The magnetic properties of the Gr and its composites are very challenging due to the absence of d and f shell electrons, which are accountable for the ferromagnetism. The theoretical and experimental studies infer that magnetism can be explored only in specified circumstances. Magnetism is attributed by density functional theory (DFT) calculations to the confinement of spin-polarized electronic states in Fermi energy levels. In honeycomb nanostructured, Gr "zig-zag" edges possess magnetic moments while zero magnetic moments are recognised at the "armchair" edge [283]. However, the temperature-dependent magnetic moment is also produced due to the point defects in the Gr lattice. It is found in the form of missing carbon from the continuous lattice or additional doping or functionalization on the surface to create vacancies [283 - 290]. Ion irradiation of atoms is bombarded on the carbon lattice to create defects, and it is susceptible to generating magnetism. The ferromagnetic behaviour at (room temperature) RT in Gr-based materials needs great attention to the inference of the doubts as well as the validity of results along with reproducibility. To get appropriate results, extra care is necessary to protect against impurities and contaminants [291]. Hence, we have initiated GO functionalization by a chemical approach to induce magnetic behaviour at RT. Understanding the thermal behaviour of defected Gr is closely related to magnetism.

Electrocatalysis and Photocatalysis For Energy Applications

Electrocatalysis was initiated by Kobosev and Monblanowa in 1936 [292, 293], to explain the electrochemical reactions which occur at the electrode surface. The

catalytic activity of the Gr can be modulated by various dopants like N, S, or O on the surface. The heteroatom dopants affect the electronic charge and spin density, which determine the catalytic activities. The electrocatalytic reactions of heterogeneous Gr have the efficiency to act as an intermediate or a reactant to interact with the electrodes. Also, the catalytic activity depends on the properties of the electrode like surface area, electron density, and thermal stability. To investigate electrocatalyst binding efficacy with electrode surfaces and to investigate new electrocatalytic applications. Pyridinic and quaternary N are the main dopants of chemically modified Gr. Several N-containing species are useful for doping on the Gr surface to explain the oxygen reduction reaction (ORR) [292]. The consumption of fuel cells (fcs) converts chemical energy into electricity. In ORR, the H_2 gas is produced at the anode. It splits into electrons and protons by a hydrogen oxidation reaction (HOR) in which the proton is diffused at the cathode with the motion of electrons throughout the cell to generate electricity. Consequently, the presence of cathodic O_2 reacts with protons and electrons to generate the water, which is generally known as ORR. Another electrocatalytic property of Gr-based materials is termed oxygen evolution reaction (OER), in which renewable natural energy is converted into chemical fuels like hydrocarbons and hydrogen energy (methanol, formic acid, methane, and butane, *etc*). OER is an excellent source of energy storage [293 - 300]. In OER, the water splits into H_2 and hydrocarbons by the reduction of CO_2. The mechanistic path of OER involves the generation of O_2 at the anode, which is important for energy storage devices like batteries, solar cells, and reversible fuel cells [293 - 300]. OER has an essential type of kinetics produced by numerous proton-coupled electron-transfer steps, which are successively made possible by the use of an active electrocatalyst to increase the reaction rate [301 - 304]. The noble metal oxide-based electrocatalysts act most efficiently [305 - 308], but due to the high cost of materials, a lot of transition metals have been applied as alternatives [303, 309, 310]. Thus, cost-effective heteroatoms doped with Gr have recently been reported for an efficient and novel class of electrocatalyst [302, 311]. Also, heterogeneous and homogenous electrocatalysts have attracted attention for OER applications due to their active electrocatalytic centres and simple OER mechanisms [304, 312 - 315].

Due to the availability of limited natural resources like petrol, diesel, coal, and others, scientists have intensified research for H_2 energy production. The accessibility of H_2O is much greater on earth than on water, which is only a workable and clean resource to produce H_2 energy in the future as an excellent source of energy within locally available resources. However, the extreme temperature (2000 °C) is required for water dissociation to produce H_2 and O_2 while avoiding instant recombining capability.The small overpotential is required for H_2O splitting to produce H_2 *via* the cathodic HER pathway of electrocatalytic

performance at ambient circumstances [293, 316]. The most effective platinum-based electrocatalyst exhibits potentially effective HER, but its high cost and lack of robustness prevent it from being commercialised [317, 318]. Therefore, scientists are highly motivated to identify alternatives to Pt-based electrocatalysts that are cost-effective, highly competent, and most durable for HER. A lot of investigations have been completed. But some are in continuation in the same direction. Transition metal-based homogenous or heterogeneous materials *e.g.* W, Co, Mo, Ni and their various derivatives like nitrides, phosphides, carbides and sulphides have been discovered, despite their corrosion vulnerability to acidic and basic electrolytes [319 - 323]. The preparation of the membrane electrode by an assembling method in which the powder form of catalyst is dissolvate in solvent with binders, subsequently forming ink on the surface with the support of copper foil and glassy carbon. As a result of the inevitable accumulation of catalyst mass and detachment from its chemical composition during the gas-based progression of HER, the dried membrane electrode has excellent catalytic activity as prepared [324, 325]. The electrocatalyst performance depends on the surface morphology, chemical constituents, pore size, electronic homogeneity or heterogeneity. Also, the architecture applied for the electrode preparation is important for HER applications.

The scientific community has focused on photocatalytic methods for photon-based energy generation in various chemical reactions. This energy solves the major global problems of pollutant remediation like water purification from toxic chemicals and dye degradation [326 - 332]. Simultaneously, it produces solar energy as a fuel substitute [298]. Photocatalysis occurs in the solar cell as a chemical bond that can be utilized in the future for various uses. Thus, photocatalysis is applicable, but there is a lack of efficiency for practical industrial application. Photocatalysis is an energy-storage device-based process. Therefore, a lot of procedures have been applied to enhance the photocatalytic activity of semiconductor-based photocatalysts, like architecture designing of materials [333, 334], doping of homo or heteroatoms [335, 336], metals and synthesis of semiconductor composites [337]. (Hydroxyl radical) attacks on organic pollutants like dyes to breakdown into nontoxic or less hazardous units that are released in gaseous form (CO_2, NO_2, N_2O, and HCO_3) and as H_2O also [327 - 332]. The toxicity of various metal-based photocatalysts forced researchers to develop metal-free carbon-based materials, especially heteroatom doped Gr, constituting carbon, nitrogen, oxygen, sulphur, and boron. So, a heterogeneous gr enhances the photoefficiency and degradation rate of organic pollutants. It makes the environment a benign water resource for the biotic community [329].

In conclusion (Fig. **6**), recent developments in the development of heteroatom-doped Gr-based materials have had a tremendous electrocatalysis application for

HER, OER, ORR, photocatalysis, and sonocatalysis to make energy storage devices: batteries, superconducting materials, and imprinting chips. Therefore, the excellent behaviour of Gr and its derivatives in many research areas has attracted us to initiate this research work. The chemically modified Gr-based materials explore out-of-the-box applications in the 21st century. Not only Gr but also GO and its derivatives have been investigated for structural studies and numerous industrial applications through several experimental conditions.

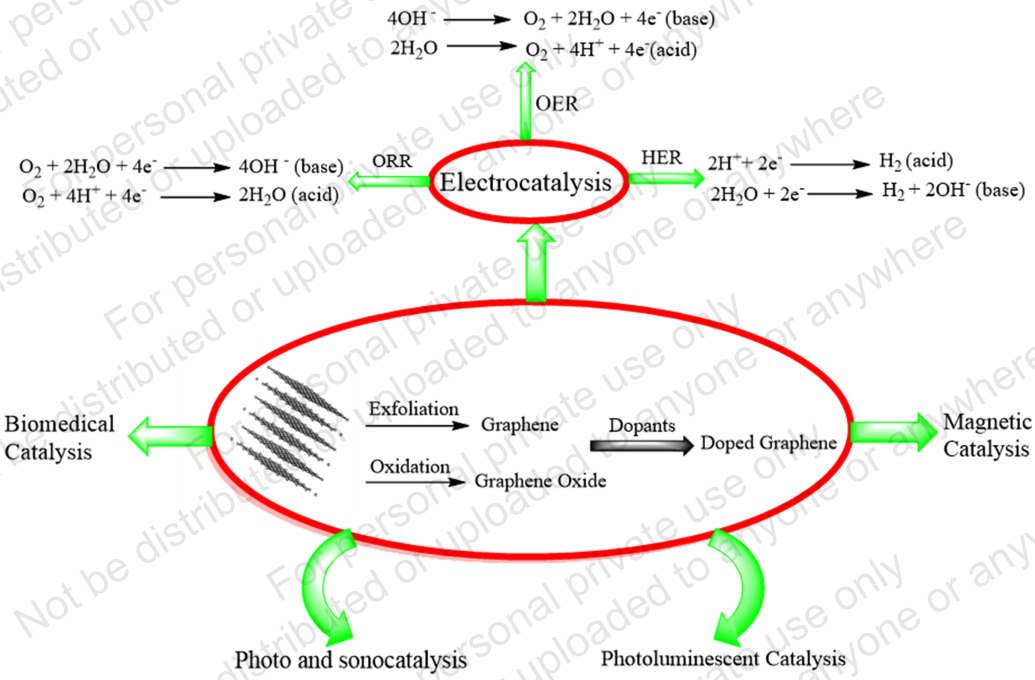

Fig. (6). Graphical representation of various catalytic performance of graphene-based materials.

We have thoroughly reviewed the initial research to explore the advanced understanding of a new dimension of the Gr and its wider derivatives and applications. Reportedly, a lot of studies have been done within the box model with certain *restrictions*. Therefore, our theme, hypothesis, and objectives have been at the cutting edge of research in the area of Gr research for enhancing industrial applications and processes.

PHYSICOCHEMICAL MECHANISM TOWARDS REINFORCING CATALYTIC PERFORMANCES

The Friccohesity is the most authentic physicochemical database to determine the structural stability, transitions, and electronic state with respect to temperature

(wrt), electrical field, magnetic field, UV light, and laser. It is found that Gt and GO are the most tunable nanofunctional materials which are structurally reorganised by these external forces. These forces could be studied with the GO sheet. The database with respect to temperature, electric field, and magnetic field, the G (Gibbs free energy) and friccohesity could be measured in certain solvents at variable stoichiometric ratios. The stoichiometric ratio determines the activity of the GO with its compositions where it is on the first order or has certain transitions in structure. This will also define the uniformity of sheet repetition. Currently, these are measured with the D and G characteristic peaks of Gt and GO with Raman spectroscopy.

However, this friccohesity tracks each and every chemical activity of the GO. The polarisation of the solvent could be studied. Normal energy could be studied. There are some intra-GO points where the solvent interacts more. This could generate the transitions in its fluid dynamics in the steady state because the force will be affected due to the different orientation of friccofluids owing to its natural flow. Hence, microfluids could also be studied. The structure of GO has an intersheet binding force which makes it difficult to weaken the intersheet Van der Waals force (ISVF) through the wet reaction procedures. As a result, before proceeding with the Gt oxidation, it could be treated with a suitable nondestructive solvent with mild interaction, allowing dipolar tuning in the ISVF, and the sheet could be slightly free with a higher surface area (HSA). The HSA develops low activation energy and higher activity. Thus, the soaked Gt could be the most economical model. There could be the possibility of reacting systems. Solvents should be explored for use before adding real reacting species. Different solvents take place one by one in the reaction medium. These could be studied to fix their impact on their interaction with ISVF. These forces are the key factors which are responsible for the sheet's togetherness. These forces originated where the Gt sheet was developed initially. At the normal energy scale, mixed solvent could also be used to identify specific solvated molecules dispersed within the sheets or out edges with moderate binding forces. Gt and GO sheets have specific spatial geometry to synchronise and synergize these structures. Thus, the points of functionalizing reagent create Lennard Jone potential distance The capillary sciences explore carbon-based functional nanomaterials (CFN). For checking the stability of the solvent-GO binding dynamics, van der Waals force theory (VFT) could be achieved. Further, the activation energy (Ea) with increased temperatures could be estimated to understand the economics of the GO functionalization. How much heat (q) is needed for functionalization could be studied by monodispersed GO in suitable solvents. Certain fluorescent dyes could also be added to understand the real science of their electronic linkages mutually. The activity coefficient could also depict the electrolyte behaviour of the GO solution in a specific solvent. The capillary action develops a remarkable alignment to have a

favourable geometrical orientation to receive maximum photons for photocatalysis of the materials. The friccofluids are different microfluids. Hence, more surface area is obtained by orienting the thinnest flat surface capillary so that it seems monodispersed . However, there could be a maximum frictional force. There is gradient flow where the GO is automatically sparsely dispersed and represents the photon O_2 cellular forces. The area of GO distribution for better electronic activity reflection investigates the various catalytic performances.

CONCLUSION AND PERSPECTIVES

Since inception, carbon nanomaterials have attracted enormous attention due to their extraordinary properties, moldability, and applications. Therefore, along with the natural allotropes of carbon, the artificial allotropes such as Fullerene, CNT, and Graphene have grown extensively in the last few decades to replace metallic devices to store energy. Because of their unique synergistic effects and physical properties such as optical, electrical, thermal, mechanical, piezoelectric, bionics, and supercatalytic, surface-modified carbon materials (SMCM) have become significant in the generation. The synergistic impacts of SMCM have emerged as the new avenues for biomedical application and catalytic activity with green environmental impact. The synthesis of graphene and surface-modified graphene oxide has both unlocked the latest thrust area in material sciences for space applications. The robust chemical approach for the surface modification of GO has been developed *via* direct amidation. Functionalized GO for semiconductor formulation has resolved the challenges to capturing solar energy. The sonochemical approach is employed for the greener surface modification of GO with unique edge intensities to design novel and state-of-the-art superconductor nanomaterials. The mechanism and outcome both lay a foundation for the formation of mechanistic intermediates with quasistatic irreversible and reversible states. For an insight into structural confirmation, the various high-end and sophisticated instrumentation techniques like ultraviolet-visible spectroscopy, FTIR, TGA, XRD AFM, SEM XPS, and HRTEM have been the assets to illustrate the sheet structures of the GO with an eye on ridging eutectic electronics for designing high-intensity CV (cyclic voltameter) sensors. Upgrading carbon footprints through surface plasmon resonance (SPR) and upconversion nanoparticles (UCNPs) out of the newly prepared functionalized graphene oxide (f-GO) could lay a foundation for the multifunctionalities for advanced and thermodynamically and kinetically stable nanoemulsion for stable electronic and heat-conducting nanoparticles for sensing thin-film technology.

Abstract: In recent years, the progress of doped carbon catalysts (such as graphene-based nanocomposites), has attracted the tremendous attention of the scientific community because of their broad area of applications involving unique mechanical, electrical and industrial chemical production processes. The catalytic nature of metal-doped graphene-based nanocomposites has significantly improved, and provides alternatives to traditional transition metal-based catalysts. In addition, the progress of simple and easy synthetic approaches for graphene-based nanocomposites provides a wide range of opportunities for the synthesis of graphene-based nanocomposites *via* incorporating various metal or polymer-based nanomaterials for diverse applications. In this context, the recent development in the synthesis of graphene-based nanocomposites, their properties and applications are summarized in this chapter. The future insights and challenges towards the design and utilization of graphene-based nanocomposites with decent stability and enhanced catalytic performance are also outlined in this chapter.

Keywords: Electrochemical Biosensor, Graphene, Graphene Nanocomposite Catalysts, Graphene Oxide, Reduced Graphene Oxide.

INTRODUCTION

Since the discovery of carbon-related catalysts, the hydrocarbon-based compounds such as activated carbon, carbon fibers, graphite, and graphite-intercalation compounds, have gained significant attraction from chemists, in the last decades. Nowadays, carbon-based materials like graphene-based nanomaterial synthesis have become an attractive field in chemistry, physics, biology, and

materials science [1]. Graphene is a two-dimensional carbon-based material having a single layer of sp^2 hybridized bonded carbon atoms that are closely packed in a honeycomb lattice [2]. Since the remarkable work of Prof. Novoselov's group in carbon-based chemistry research, the fast development in graphene-based research has envisioned the great potential of graphene in optoelectronics, nanoelectronics, electrochemical drug delivery, and biosensor applications due to its unique 2D structure, excellent electrical capacity, high adsorption susceptibility, high mechanical strength, and high thermal conductivity [3 - 5]. Although graphene sheets were well explored in fundamentals by a physicist at the discovery time, graphene metal-nanocomposites are drawing more attention to real applications for industry [6 - 9]. Until now, various synthetic procedures, such as covalent as well as non-covalent methods, electrochemical, micro-mechanical, solvo-thermal, chemical oxidation–reduction, chemical vapour deposition, photochemical reaction, physical deposition, and mixing [10 - 14] have been fabricated for the synthesis of well-defined functional graphene-based nanocomposites [15 - 20]. It was investigated that the graphene-based sheets can be doped with several components such as metal, metal oxides, or polymers [15, 21, 22] and developed as graphene-based-hybrids which can be employed in multiple applications [23 - 29]. In this view, extensive efforts have been devoted towards the study of graphene-based hybrids and many reviews on their design, development, synthesis, properties, characterization, and applications in recent decades are documented [29 - 32]. The significant potential growth of graphene-based nanocomposites toward their application in a variety of fields motivated us to present its synthesis, properties, and potential applications in a single chapter.

It is well established that the design of a heterogeneous catalyst plays an important role in its catalytic activity [33, 34]. As a new carbon family member, the extraordinary properties of graphene-based nanocomposites provide an ideal catalytic support [32, 35]. Therefore, we hope that this chapter will draw significant attention to the recent developments and advancements in the synthetic protocols and catalytic utilization of graphene-based nanocomposites. It is noteworthy that almost all graphene supports in the nanocomposites are developed *via* chemical reduction–oxidation methodology. The catalytic reactions, which are demonstrated, are an extension of the model reactions towards industrial-based reactions and the utilization of non-selective reactions towards more challenging and selective hydrogenation, coupling, oxidation, or reduction reactions. In the present chapter, a brief overview of the characteristic synthetic approaches and catalytic potential of graphene-based nanocomposites is presented, along with the enhanced catalytic behavior. A summary of some of the scientific opportunities and challenges is also presented at the end of the chapter.

APPROACHES TOWARDS GRAPHENE-BASED NANOCOMPOSITES SYNTHESES

Many versatile synthetic approaches have been documented to synthesize the graphene-based nanocomposites, such as covalent/non-covalent interaction, photochemical reactions, chemical/physical deposition or mixing, hydrothermal/solvothermal growth, electrophoresis, and electrochemical deposition. These developed approaches have several advantages as well as limitations, along with the improved recent development of specific graphene nanocomposites by adoption of appropriate preparation methods.

Non-covalent Interactive Approach

Non-covalent interaction is a leading applied methodology to design and synthesize graphene-based nanocomposites. Non-covalent association of organic and inorganic species with graphene leads to the attachment of organic and inorganic species on graphene incorporated surfaces. *in-situ* Small molecules, such as surfactants and polymers, are bonded to graphene surfaces *via* - stacking and/or hydrophobic interactions, providing an important way to modify graphene surfaces for graphene nanocomposites [36 - 40]. Because of the strong -stacking interaction with the graphene sheet of the pyrene moiety in the molecule, Xu and colleagues used PB- to synthesize enhanced hydrophilic graphene [40]. This was provided by *in-situ* chemical reduction of GO by hydrazine in the presence of 1-pyrenebutyrate (PB-).The resultant water-soluble graphene can be utilized to develop large scale conductive graphene films with higher conductivity in comparison to graphene oxide.

Metal ions can also be doped in graphene sheets through non-covalent congregation of graphene to form 3-D composites or hydrogel [41, 42]. For example, graphene oxide and metal precursors are hydrothermally decomposed to furnish three dimensional graphene-supported metal nanocomposites. Novel metal nanocomposites (Ag, Au, Pd, Rh, Ir, or Pt) on graphene material exhibit active sites, which enhance the porosity in graphene metal composites. The catalytic activity of 3-D composite with respect to Heck reaction has shown excellent and selective physical behavior [41]. GO sheets also undergo metal ions promoted self-assembly based reaction *via* the reduction of GO and produce magnetic Fe_3O_4 nanoparticles with macroscopic graphene based nanocomposites [42].

Covalent Interactive Approach

Another method that can be used to design and synthesis graphene nanocomposites is covalent reaction. Ionic liquids, polymers, porphyrin,

azidotrimethylsilane, *p*-phenyl-SO_3H, perfluorophenylazide (PFPA), and organic nitrite can all be covalently bonded to graphene *via* atom-transfer radical polymerization, amide-bonding, or click chemistry reaction. There are limited examples reported in the literature for the synthesis of graphene metal composites *via* covalent assembly [43-45].

Click chemistry is one of the best methods for the formation of covalent bond with metal composites and graphene surfaces. Various photo-induced moieties such as ruthenium-phenanthroline and zinc-porphyrin chromophores can be attached to graphene sheet using click chemistry. Firstly, the graphene surface was modified by unsaturated moieties *via* exposing alkyne groups followed by click chemistry reaction. In the result, these hybrids showed significantly improved photocurrent responses [46].

In-situ Chemical Electroless Deposition-based Approach

In the last few years, various efforts have been made to deposit nano-objects on graphene sheets to fabricate nanocomposites *via* chemical electroless deposition. Specific nanorod, nanoparticle and nanosheet can be fabricated *via* doping of metal on graphene surface, through *in situ* chemical deposition method, of the selective precursors. These process are straight forward and convenient for designing of a large number of graphene-based nanocomposites using metal oxides, metals and dichalcogenide precursors, such as, Au, Pt, Ag, Cu, TiO_2, Fe_2O_3, Mn_3O_4, SnO_2, and CdS [47 - 55]. Using the electroless chemical deposition method, Li *et al*. created graphene-based bimetallic nanocomposites with improved electrochemical surface area [48]. High-quality 3D-bimetallic nano-dendrites Pt-on-Pd were doped on graphene surfaces in two steps (Fig. **1**). Pt precursors (K_2PtCl_4) were reduced by earlier doped Pd-NPs on graphene-based material and fabricated into branched Pt-nano-dendrites with the number of branches being tunable with a synthetic framework [48]. Similarly, Ag-deposited graphene nanocomposites were created by heating a silver nitrate-graphene oxide aqueous solution at 75°C or by in situ reduction of silver precursor in the presence of GO by glucose or other reducing agents [50, 51, 56]. Copper-based graphene composites were also created by heating a copper precursor in the presence of graphene oxide and potassium borohydride [57].

The resultant Cu-nanoparticles are well dispersed on a graphene sheet having a diameter of about 20.8 nm. In another report, graphene-based macroscopic hydrogel-iron oxide nanocomposite with robust interconnected three-dimensional frame was constructed by the synergistic effect *via in-situ* reduction of graphene oxide from ferrous ions [42]. The amount of reducing agent and pH value play a very significant role in the synthesis of graphene-based nanocomposites. In

another investigation, TiO_2 deposited graphene nanocomposites have been designed and synthesized by *in-situ* hydrolysis of absorbed Ti (IV)-butoxide on rGO surfaces with oxygenated functional groups [74]. To achieve both better deposition and high conductivity of TiO_2 NPs, the oxidization time in the chemical exfoliation process was essential [53]. *In-situ* Metal chalcogenides like cadmium sulfide-NPs can be produced by *in-situ* chemical deposition on graphene sheets [58]. CdS nanoparticles were also synthesized from cadmium nitrate and CH_4N_2S at 150 °C heating in microwave irradiation [59]. This method was also used to synthesize graphene-zinc sulphide nanocomposites from zinc ions and H_2S gas reactions [54].

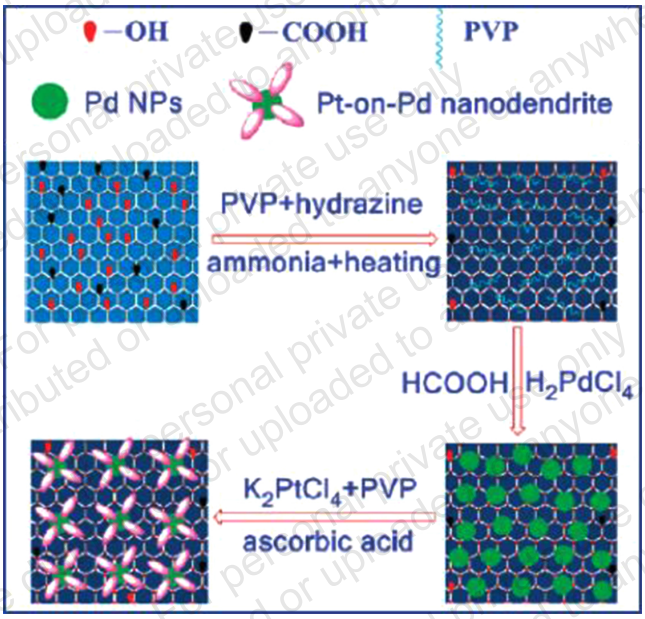

Fig. (1). Schematic representation for designing graphene nanosheet/Pt on Pd bimetallic nano-dendrite hybrids. (Reproduced with permission from Ref [48]. Copyright 2010, American Chemical Society).

Solvothermal and Hydrothermal-growth Based Approach

Solvothermal and hydrothermal methods are also extensively employed to construct graphene nanocomposites. Due to high pressure in solvothermal and hydrothermal methodologies, the acquired materials have close covalent network between deposited composites and graphene, which shows various useful applications.

To fabricate graphene metal composites by solvothermal or hydrothermal methodology, the metal/metal oxide precursor is mixed with graphene or GO in a solution followed by solvothermal/hydrothermal deposition of the precursor on

graphene sheet at high pressure in an autoclave. Solvothermal and hydrothermal processes are very flexible and can be used to design various kinds of nanomaterials (Fig. **2**) [60 - 65].

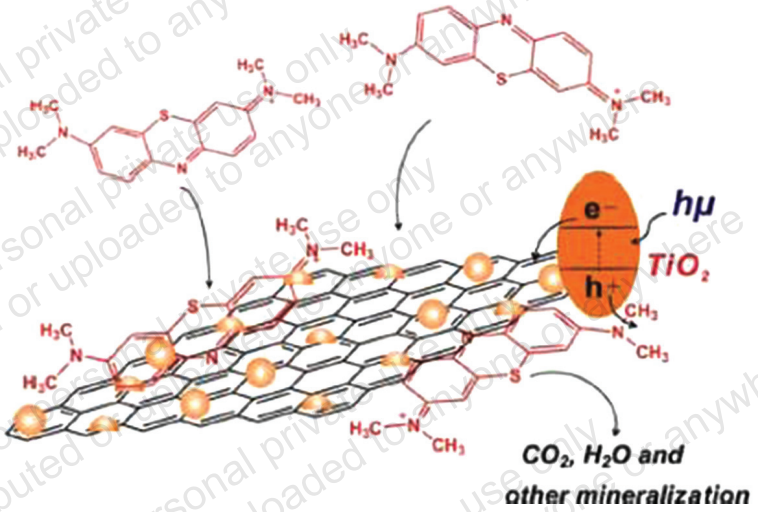

Fig. (2). Schematic representation of P25 nanoparticles and photodegradation of methylene blue (MB) over P25-GR. (Reproduced with permission from Ref [64]. Copyright 2010, American Chemical Society).

Metals like Ag and Pt-Ru, metal oxide (TiO_2, SnO_2, VO_2, Mn_3O_4), metal chalcogenides (*e.g*: ZnS, SnS) and complex compounds ($LiFePO_4$) based nanocomposites have been successfully decorated on the 2D carbon layer of graphene with well controlled solvothermal methods. Ye and his co-workers have reported a hydrothermal synthesis of reduced graphene oxide based Ag-nanocomposites by using ascorbic acid as a reducing agent and silver nitrate and graphene oxide as precursors [60]. Yoon and co-workers fabricated platinum–ruthenium (Pt-Ru) nanoparticles on graphene sheet *via* a hydrothermal process and the composites showed improved tolerance towards poisoning issues of oxidation of methanol with enhanced electrocatalytic activity [61].

Metal oxides are also used to synthesize graphene-based metal oxide composites on 2D carbon sheets by hydrothermal or solvothermal assembly. Zou *et al.* utilized seed-directed hydrothermal process to synthesize a large number of graphene-based metal oxide (such as TiO_2, ZnO, MnO_2, CuO, and ZrO_2) nanocomposites *via* designing a novel series of metal oxide-graphene-metal oxide hetero-structures. The hetero-structures exhibit four times increased photo-catalytic properties compared to pure metal oxide nanoparticles [62]. TiO_2 attached graphene nanocomposites were synthesized from GO and a reducing agent using a hydrothermal process (Fig. **3**) [63]. The crystal facets of TiO_2 nano-

objects in graphene based-nanocomposites, can also be controlled in a hydrothermal fashion [66]. Recently, graphene-based TiO_2 nanotubes and TiO_2 nanosheets with exposed facets were developed under a hydrothermal process in alkaline solution/ aqueous ethanol (Fig. **3**) [67, 68].

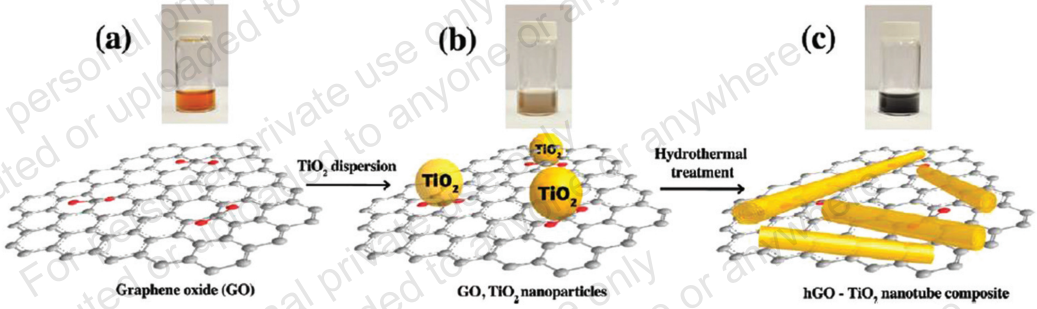

Fig. (3). Graphical presentation of the synthesis of TiO_2 nanotubes on rGO sheets. The GO sheets (a) coordinated with TiO_2 nanoparticles (b) converted to TNTs on hGO (c) The digital images show the color variations of the aqueous dispersions in each stage. (Reproduced with permission from Ref [68]. Copyright 2012, American Chemical Society).

After 2010, several research groups broadly investigated the synthesis of TiO_2 and VO_2 nanotubes, MoO_3 nano-objects, Mn_3O_4 and Fe_3O_4 nanoparticles having spherical geometry and hollow interiors with graphene *via* hydrothermal approach (Fig. **4**) [13, 65, 68 - 71]. Graphitic layers decorated with metal chalcogenides were also synthesized by solvothermal method. Cao and his co-workers have reported synthesis of CdS quantum dots attached to graphene sheets [72]. The nanocomposites formed have demonstrated tremendous performance in electron transfer from quantum dots (QDts) to graphene surfaces and have significant importance in optoelectronic materials. Later on, Gong *et al.* adopted the same methodology for the fabrication of graphene CdS nanocluster for hydrogen generation from water [72]. ZnSe mixed graphene nanocomposites were designed and synthesized by one-pot hydrothermal based methodology by using graphene-oxide (GO) and zinc-selenide (ZnSe) as precursors. The nanobelts were deposited from GO followed by heating at 180ºC temperature for 12 h under a solvothermal approach [73]. In addition, the complex compounds, such as $Li_4Ti_5O_{12}$, $LiFePO_4$ and $Bi_2WO_{6;}$ were also synthesized by hydrothermal and solvothermal processes [74 - 76].

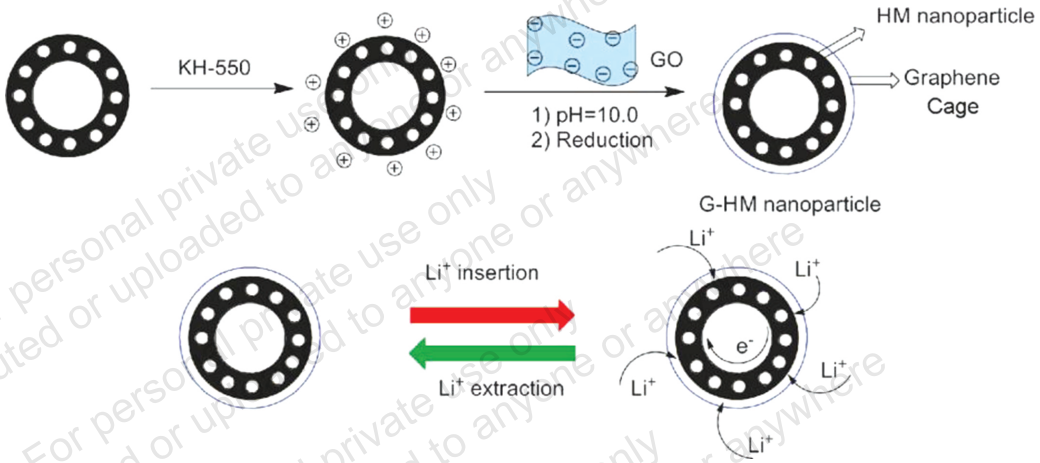

Fig. (4). Schematic illustration of the fabrication process along with the structure of the resulting graphene nanocomposite. (Reproduced with permission from Ref [69]. Copyright 2011, American Chemical Society).

Microwave- assisted Approach

Under this approach, microwave irradiation (MWI) is widely utilized towards the design and synthesis of graphene-based nanocomposites [8, 77, 78]. Particularly, the construction of graphene-based metal nanocomposites by *in-situ* reduction of various metal salts and graphitic materials, exhibited significant catalytic activity. In 2009, Hassan *et al.* reported the scalable synthesis of RG/NP composites by microwave-induced reduction [79]. This strategy represents a fast reduction of graphene oxide with several reducing agents in water and/or organic media, and the instantaneous reduction of GO with metal precursors furnishes the construction of metallic/bimetallic NPs doped graphene sheets. Under MWI conditions, metal- attached graphene nanocomposites of Pd, Cu, Ag, and Au have been made by *in-situ* reduction of appropriate metallic salts (Pd nitrate, $HAuCl_4$) and graphitic material with several reducing agents like ethylenediamine, ammonium hydroxide, and hydrazine hydrate [78]. *In-situ* reduction leads to homogeneous dispersions of nanostructures on graphene sheets *via* specific interaction and physical mixing between the graphene sheets and nanocomposites. In addition, the *in-situ* MWI approach has also been applied to fabricate graphene-based metal nanocomposites such as Graphene–SnO_2 nanocomposites. (Fig. **5**) [80]. Liu *et al.* investigated improved conditions for the synthesis of ZnS nanospheres on graphene, and the reaction was optimized in an aqueous medium induced by MWI [81]. Additionally, in 2014, a MWI-based approach for an ionic liquid supported Pd-Pt nanostructures on HRG sheets was investigated [82].

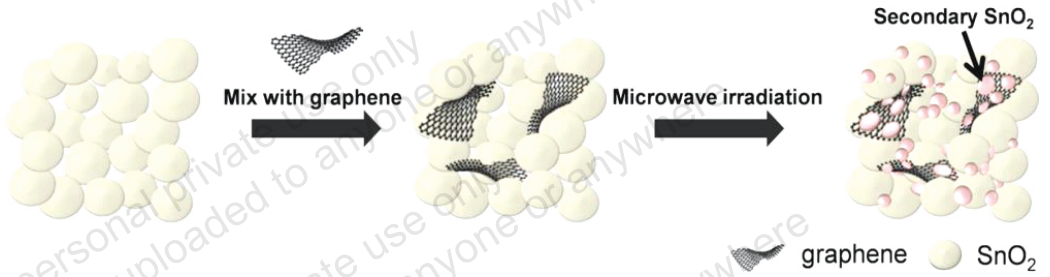

Fig. (5). Schematic illustration of the morphologies of the graphene−SnO_2 nanocomposites developed by the MWI. (Reproduced with permission from Ref [80]. Copyright 2011, American Chemical Society).

Electrochemical and Electrophoresis Deposition-based Approach

Electrochemical and electrophoresis depositions are another widely used methododologies for the synthesis of graphene-based metal nanostructures. Metal salts and oxides easily mix with 2D carbon layers by electrochemical assemblies [83 - 89].

Using electric current, electrochemical reduction of metal nanomaterial was also discovered. Some semiconductors such as Cd-Se was electrochemically doped on graphene surfaces and resulted the graphene nanocomposites. ZnO nanoparticles were also deposited on conductive reduced graphene oxide (rGO) under electrochemical deposition assembly [83]. In brief for the first time, a constant potential was used with ZnO on reduce graphene oxide for the synthesis of nanocomposite.

The conductivity of rGO has a strong influence on zinc oxide-based graphene nanocomposite. Particle-shaped nanocomposites were synthesized with rGO having low conductivity, whereas the hexagonal nanorods were constructed with rGO having greater conductivity. A graphene-based MnO_2 nanocomposite was also fabricated by electrochemical method (Fig. **6**) [85]. In 2011, Graphene composite having Cu_2O/ZrO_2 was also prepared by using electrochemical methodology [86, 90]. Metals like Ni, Cu, and Pt were doped on graphene sheet by an electrochemical approach [87, 91 - 93]. Yang *et al.* developed a mixed metal Au-Pd nanocomposite on graphene surface by constant-potential reduction using electrochemical approach with $HAuCl_4$, $PdCl_2$, and 0.1 M KCl [93]. In 2013, Ma and co-workers fabricated graphene-based NiOH nanocomposite under the electrophoresis method with Ni^{2+} ions and GO colloidal solutions. The positively charged graphene oxide, by nickel ions, was deposited on substrates *via* electrochemical reduction of GO to rGO under negative current [94].

(f) Nyquist plots demonstrating the corresponding impedance curves for assembled ECs (observed after every 1000 cycles). (Reproduced with permission from Ref [85], Copyright 2011, American Chemical Society).

Chemical-vapor Deposition (CVD) Based Approach

Chemical-vapor deposition is another valuable approach for constructing graphene-based nanocomposites. Normally, graphene is utilized as a base material in the normal chemical-vapor deposition (CVD) based approach for the synthesis of graphene based hetero-nanostructures having other materials [95 - 102]. In 2009, Kim and his co-workers fabricated graphene-based ZnO nanoneedles employing vapor-phase epitaxy [95]. ZnO deposited graphene heterogeneous nano-objects were also synthesized by tuning the temperature in CVD assembly [96]. Recently, Fan and coworkers published a report on the CVD induced 3D CNTs/graphene sandwich compound prepared by using graphene oxide with uniform catalysts for CNT growth (which improved surface area) [97]. In the year 2010, pillared graphene mixed CNTs were also fabricated [98]. The same CVD processing was used to make metal-doped graphene-based CNTs composites and three-dimensional graphene mixed CNTs carpet micro supercapacitor electrodes [99, 100, 102]. Tavakkoli and colleagues recently developed a one-step catalytic CVD assembly to make a highly graphitized/CNT hybrid-material that was doped with single atoms (N-Co-GF/CNT). The enhanced surface area composites have

mesoporous structures, which facilitates oxygen mass transfer within the catalyst film and also act as an electrocatalyst for oxygen reduction in basic medium [101].

Photochemical- based Approach

Photochemical reaction is another approach for designing and synthesizing graphene-based metal-nanostructures [103 - 111]. Under UV light irradiation, graphene surfaces can be modified with reducing agents or metal precursors, which may provide the graphene-based nanoarchitectures. For example, the graphene-based TiO_2 nanocomposite was fabricated by mixing GO and TiO_2 NPs in ethanol under UV irradiation conditions. The photoactive TiO_2 transfers the electrons to graphene oxide and affords reduced graphene/TiO_2 nanocomposites. (Fig. **7**) [103].

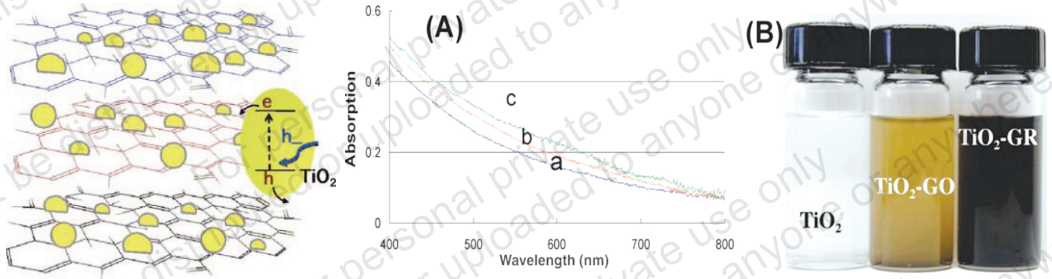

Fig. (7). (**A**) TiO_2-graphene nanocomposite having response in UV excitation/absorption spectra of GO and TiO_2 in ethanol suspension (a) before UV irradiation, (b) after 5 min (c) after 15 min under UV irradiation; (**B**) The color change of TiO_2 nanoparticles of 0.5 mg/mL GO of 10 mM solution before/ after UV irradiation. (Reproduced with permission from Ref [103], Copyright 2008, American Chemical Society).

In 2011, Amal and his co-workers adopted the same strategy to fabricate WO^{3-} and $BiVO^{4-}$ based graphene nanocomposites by irradiation with light amongst their precursors and graphene oxide [104]. Additionally, in metal nanoparticle based graphene nanocomposites, the precursors were doped on 2D carbon sheet under photochemical irradiation [104, 106 - 109, 111]. A photochemical strategy was also applied for the photolysis of phosphor-tungstic acid (PTA) to reduce GO for graphene based Au, Ag, and Pt NPs synthesis [105].

At the same time, two- step photochemical process was also developed for the dispersed noble metals (Pd, Ag, and Au) NPs on graphene sheet in dimethylformamide solvent. In the first step, the photolysis of phosphor-tungstate provides reduced graphene from graphene oxide. The noble metal ion precursors were doped with above metals to fabricate graphene-nano composites [106]. In

2012, Chen and his colleagues used an Hg lamp (450 W) to initiate the photochemical reaction for the synthesis of Ag/rG nano-structures using a mixture of $Ag(NH_3)_2OH$ complex and GO [107]. In the same year, the Ag NPs were also deposited on graphene oxide using similar methodology [108]. Ag NPs deposited on graphene oxide and Pt-graphene based-nanocomposites were synthesized *via* same method without using any reducing agent (Fig. **8**) [109 - 111].

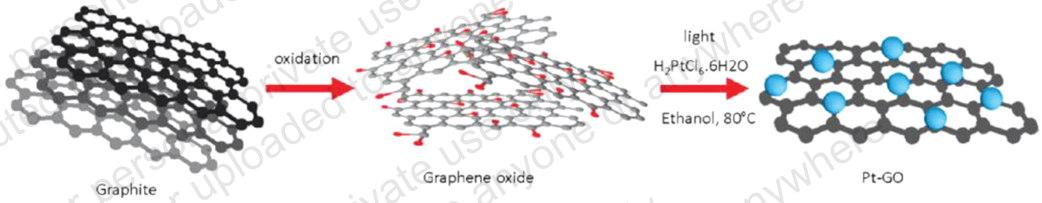

Fig. (8). Schematic depiction of light mediated Pt-Salt reduction on GO-sheet in ethanolic solution. (Reproduced with permission from Ref [110]. Copyright 2012, American Chemical Society).

Physical Deposition/Mixing Based Approach

The straight forward and simple process to construct graphene based-nanostructures, directly attached on 2D carbon sheet, *via* physical loading (physical vapor deposition/atomic layer deposition) is also discovered [112 - 116]. Metal oxides like Al_2O_3 was physically loaded on graphene sheet with atomic layer deposition (ALD) assembly (Fig. **9**) [112]. Metal based nanostructures were also doped physically on modified graphene surfaces under chemical environment by physical-vapor deposition based methodology [113]. The NPs growth on 2D (two dimensional) carbon layer was illustrated below, which exhibits significantly difference of activity for diverse metals (Ag, Fe, Au, Pt, Pd, Ti). Physical mixing is also one of the simplest approaches to synthesize the graphene-based nanocomposites. In the general procedure, the three-dimensional graphene material was obtained, when $LiFePO_4$ nanoparticles were loaded on graphene sheet by using annealing and spray-drying methodology [114].

Alternatively, the commercially available $LiFePO_4$ material was deposited on graphene sheet through a dropwise loading of $LiFePO_4$ particles at 180 ºC in DMF solution. This process was stimulated by a non-covalent interaction between the graphene surface and the amorphous carbon shell of $LiFePO_4$ particles. These modifications resulted improved stability and more efficient capacity of lithium battery of $LiFePO_4$ [115, 116].

PROPERTIES AND APPLICATIONS OF GRAPHENE-BASED NANOCOMPOSITE CATALYSTS

The diverse nature of graphene-based nanocomposites exhibits a huge range of properties towards various aspects. The novel properties and applications of graphene-based nanocomposites are the main criteria for catalyst design and synthesis. Therefore, only those potential graphene-based nanocomposites that exhibit significant catalytic potential are shortlisted and discussed in the present chapter.

Based on theoretical and experimental calculations for graphene and graphene-based nanocomposites (using carbon nanotubes (CNT)), the properties and applications were found to be outstanding with respect to several aspects. In graphene, the carbon atoms are arranged hexagonally, which results in a 2D honeycomb scaffold. While the strong bonds in graphene sheets lead to the stability and rigidity in hexagonal structures, the other out of plane π bonds provide interaction between different 2D carbon layers [117]. In addition, another significant property of graphene is the adsorption on the surfaces. It was found that the adsorption and interaction between 2D carbon surfaces and adsorbed objects are unique and specific parameters towards the design and synthesis of the

graphene-based nanocomposites. The theoretical calculations are of paramount importance in order to emphasize this property of graphene sheets. The stable configuration of embedded metal atoms in graphene displays the charge transfer between graphene and the adsorbed metal atoms. Generally, the binding of the adsorbed metal atom on graphene takes place *via* three sites of symmetry: a) at the center of a hollow hexagon (H); b) at the center of a C-C bond bridge (B); c) and directly on the carbon atom top (T) [118]. In 2010, Hu and his coworkers developed a good correlation between the adsorption of a huge number of doped metal atoms on graphene surface using DFT energy calculations [119]. They outlined that hollow hexagon sites are well suited for Ti, Sc, V, Co, Ni, and Fe deposition on graphene sheet, whereas B or T are the most striking sites for metals that have a completely filled or near- to- filled d-shell (Pd, Pt and Cu). Having half-filled d-shell transition metals (such as Au, Ag and Zn) has lesser adsorption energies. The preferred adsorption site is based on the intensity of the adsorption energy, which represents the remarkable effect on the chemical bond between the graphene surface and deposited materials. So, the adsorption of these metals (such as Ag, Au, and Cu) was reflected as physisorption, whereas the adsorption of Ni, Pt, Co, and Pd showed chemisorption on the graphene sheet surface. Similar results were reported for Ag, Au and Pt metals by Tang and his coworkers [120]. In 2011, the Nakada research group discovered the migration and adsorption energies for almost all atoms in the periodic table from H to Bi (except Ln, noble gases) on 2D carbon sheets using DFT calculations. The computational data demonstrated that the chemisorption of metals includes hybridization of d-orbitals of deposited atoms with the graphene surface. For the doped atom, there is a decrease in the magnetic moment for adsorbed metal atoms compared to the isolated metal atom, which depends on charge transfer between graphene and the adsorbed atom [119]. Several other research groups have also demonstrated the relationship between chemical/biologically privileged compounds with graphene sheet or metal deposited graphene sheet [121 - 123]. On the basis of theoretical as well as experimental observations, enormous works have been documented for the synthesis of graphene- based inorganic nanocomposites, typically using transition metal/metal oxide nanoparticles [8, 32, 78, 118, 124]. Moreover, massive interest has been reported in synthesizing graphene-based nanocomposites and utilizing them for diverse applications [8, 82, 91, 100, 125].

For Energy Storage and Conversion

The discovery of novel methodologies for the manufacturing of clean energy is an interesting and more challenging area for the scientific research community. Due to the increased air pollution and global warming conditions, the development of high energy density devices for energy storage and its conversion has increased tremendously [126, 127].

As a Basic Component in Lithium-ion Batteries (LIBs)

Graphene-based nanocomposites have attracted significant popularity in the electrochemical energy storage research area because of their unique physico-chemical properties, such as enhanced chemical and thermal stability, better electrical conducting behavior and mechanical properties. Graphene-based nanocomposites have been utilized as electrode materials and investigated for energy storage and conversion devices like lithium ion batteries (LIBs), supercapacitors, and fuel/solar cells [128 - 133]. TiO_2 has gained tremendous interest in high-performance LIBs. Several TiO_2 doped nanomaterials with increased lithium storage capabilities compared to non-doped pure TiO_2 have been developed [134, 135].

In 2011, Li *et al.* investigated a simple one-pot route *via* template free self-assembly methodology to fabricate mesoporous TiO_2 nanocomposite on a graphene surface. These TiO_2 nanocomposites are mono-crystalline in nature compared to the conventionally based poly-crystalline mesoporous anatase particles. The nanocomposite exhibits a significant improvement in the specific capacity, which is 6-fold higher than the pure TiO_2 [136]. Due to the layered structure and abundant availability in nature along with the high energy density, the vanadium pentoxide (V_2O_5) has been discovered as a cathode material in rechargeable LIBs. Therefore, a huge number of V_2O_5-based graphene nanocomposites have been investigated [137 - 139]. A V_2O_5 doped HRG nanocomposite having significant electrochemical properties was synthesized *via* hydrothermal reactions [140]. Yang *et al*. demonstrated in 2011 that graphene-based nanocomposites decorated with MoO_3 act like n-type semiconductors with energy storage in electrochromic and photochromic devices [141]. It was later investigated that MoO_3-based graphene nanocomposites showed enhanced discharge capacity and an outstanding high specific capacitance activity [142]. Mn_3O_4 has been investigated as an anode material for LIBs, having higher specific capacitance than graphite [143]. In order to achieve higher capacity, Wang *et al*. produced Mn_3O_4-based graphene materials in two steps.

The hybrid nanocomposites exhibited significant high capacity of ~ 900 mA h g^{-1} as well as good cycling stability and rate capability [144]. Fe_3O_4- based graphene nano-composite was developed by Su *et al.* with excellent reversible capacity, high cyclic performance, and enhanced rate capability compared to the Fe_3O_4 nanoparticles (Fig. **10**) [145]. Zou *et al.* reported Fe_2O_3 doped graphite nanocomposites as an anode material in LIBs. This metal nanocomposite revealed a good reversible capacity (1184 mA h g^{-1}) upon cycling along with an outstanding rate capability at increased currents [146]. In addition, graphene-

based nanocomposites of Fe_2O_3 and Fe_3O_4 and other iron-based precursors (like $LiFePO_4$) have also been utilized in LIBs [146 - 148]. Moreover, Qu *et al.* made sandwich-like Fe_3O_4 doped graphene nanocomposites *via* FeOOH nanostructures with graphene [149].

As a Basic Component in Supercapacitors

Supercapacitors are utilized as brilliant energy storage materials and display enhanced power density and increased life cycle along with improved performance in comparison to common batteries. The energy storage capacity in supercapacitors contains a carbon-based EDL (electric double layer). In EDLCs, the charge storage depends on the material of electrode, because the stored energy depends on the adsorption of ionic charges. Therefore, the property of electrode material is highly responsible to increase the efficacy of capacitance of EDLCs. In this point of view, graphene as well as graphene-based nanocomposite was found to be a good alternative for making improved electrodes [150]. For example, the electrochemical capacity of RuO_2 hybrids with activated carbon, exfoliated graphite and CNTs, exhibited significant potential towards efficacy [151]. Wu *et al.* synthesized RuO_2 doped HRG nanocomposites by solvo-thermal process by varying the Ru loading amount [152]. Later on, using high theoretical capacitance, the expensive amorphous RuO_2 was replaced by cost effective and easily available $Ni(OH)_2$ and NiO [153, 154].

As an Electrocatalyst in Fuel Cells

Several graphene-based nanocomposites have been well explored as an electrocatalysts in ORR. Pd incorporated rGO nanocomposites were used as electrocatalysts in ORR along with the oxidation of alcohols in various fuel cells, such as DEFCs, DMFCs and DFAFCs [25, 155, 156]. Bimetallic Pt–Au graphene nanocomposites are an important electro-catalyst in DFAFCs fuel cells, which are also utilized for formic acid oxidation. Au loading on Pt nanoparticles has an specific effect on the direct oxidation to CO_2 from formic acid without CO intermediates [157]. Later on, Pt decorated graphene nanocomposites with perfluorosulfonic acid (PFSA) were utilized as electro-catalysts for ORR. PFSA accelerates the Pt–graphene interactions and opens more channels for H^+ on Pt surfaces, and thus generates more active catalytic property (Fig. **11**) [158]. In addition, PFSA activates the absorption of H_2O and CO on graphene composite surfaces and leads to an active Pt–OH compound's synthesis, which enables the oxidation to CO_2 from CO. Thus, PFSA-anchored HRG/Pt nanocomposites showed an enhanced catalytic oxidation of CO along with minimum electrochemical active area reduction. Rao and his coworkers discovered graphene-based Pt_3Cr and Pt_3Co nanocomposites, having 3 to 4 times enhanced catalytic activity than HRG/Pt, as electrocatalysts for ORR [159].

As an Electrochemical Sensor

Various graphene-based nanocomposites have also been used as electrochemical sensors for detecting numerous chemicals. In 2011, Du and his co-workers synthesized ZrO_2 decorated graphene composites, where ZrO_2 nanoparticles were utilized as a selective sorbent for SPE (solid-phase extraction) and detection of pesticides (such as OP pesticides and nitroaromatic OP pesticides) [160]. Graphene based ZrO_2 electrochemical sensor was also utilized for rapid extraction for analyte, due to its strong affinity to phosphorus based species. Recently, Gong and his co-workers investigated HRG/ZrO_2 nanomaterial as SPE for enzyme less methyl parathion sensing [161]. Subramanian *et al.* discovered a non-enzymatic $Ni(OH)_2$ decorated graphene nanocomposite as a sensor for glucose detection. The nanocomposite is composed of leaf-shaped $Ni(OH)_2$ (diameter =~150 nm) dispersed between the graphene layers. The sensing limit (up to 0.6 mM) having a good linear range (2 mM-3.1 mM) was attained in this study [162]. Moreover, the excellent sensing capability of graphene and the detection capability of Pd nanoparticles have been also utilized simultaneously for numerous sensing applications [163]. The enhanced catalytic property of Pd-decorated graphene nanocomposites was achieved by charge transfer from molecules wrapped on graphene surface *via* change in the electrical conductive behavior of graphene. In 2010, Johnson and his co-workers investigated graphene-based Pd nanocomposites as hydrogen sensors in fuel cells [164]. This research group prepared multi-layered graphene as a nanoribbon *via* dispersing graphite material along with functionalized Pd-nanostructure in a water-surfactant solution. The nanoribbon, having porous structure, provides improved surface area, which permits better detection of the adsorbed gas. HRG based Au-nanocomposite was investigated as an electrochemical sensor, for sensing organic species, chemicals and metallic ions (such as lead, organophosphate pesticides, hydroquinone *etc*.) [165, 166]. The quenching potential of Au-nanocomposite was utilized for the detection of lead ions in organophosphate pesticides as a chemo-sensor. The composite electrode having acetylcholinesterase, was stabilized from aqueous soluble poly-diallyldimethylammonium chloride (PDDA electrolyte) [167]. The graphene and ZnO, together exhibit electronic and semiconducting nature so, a ZnO-graphene composite was used to fabricate a highly sensitive photo-sensor [168]. Graphene nanocomposites having ZnO NPs work as visible-blind UV-photosensors, where graphene behaves as a conductive matrix and the ZnO NPs were used as a charge carrier generating a UV absorbing material also [169]. The HRG nano-material having ZnO with photoluminescence (PL) nature was explored for gas detection [170]. HRG having ZnO nanocomposites showed optoelectronic and semiconducting features [171]. The ZnO nanomaterial with luminescent nature present between the graphene layers showed sensing property for various gases (such as NH_3, CO, and NO). In addition, SnO_2 based graphene

nanocomposites with excellent selectivity and sensitivity were also developed [172].

Lu and his co-workers discovered graphene-based Pd decorated electrode, for the detection of glucose, as an electrochemical biosensor [173]. This research group modified graphene with chitosan covalently which improved the solubility and biocompatibility [174]. Dey and his co-workers reported the synthesis of graphene-Pt based nanocomposite as an amperometry biosensor for detecting cholesterol and H_2O_2 *via* catalyzing H_2O_2 oxidation and electron transfer [175]. In 2012, Chen and his coworkers fabricated Cu decorated graphene nanocomposites for carbohydrate sensing *via* reduction of graphene oxide with KBH_4. (Fig. **12**) [176].

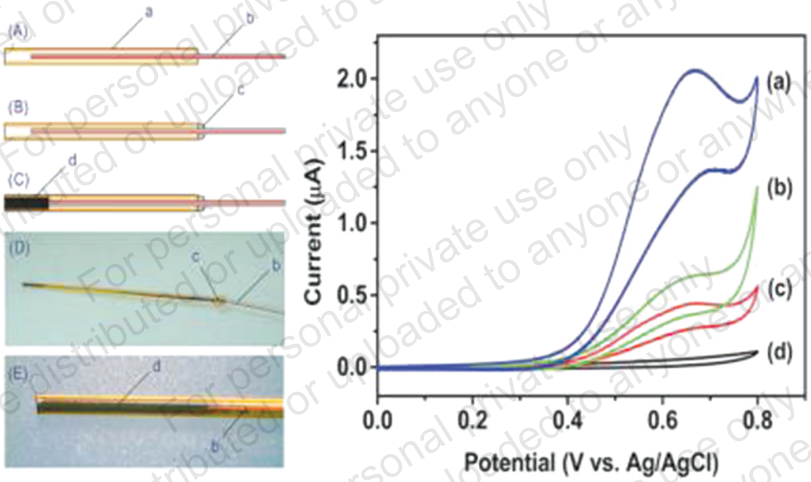

Fig. (12). (**A-E**): Schematic illustration of fabrication of graphene-copper nanoparticle composite electrode, and cyclic voltammetry diagram of graphene-copper nanocomposites. (Reproduced with permission from Ref [176], Copyright 2012, American Chemical Society).

Ag- based HRG nanocomposites were also prepared for sensing of H_2O_2, glucose and NO_2-based aromatic compounds [177, 178]. Graphene decorated with Ag nanocomposite was also explored for the detection of glucose, H_2O_2, and SERS substrate [179]. Zhang *et al.* investigated Au decorated graphene nanocomposites as an electrochemical bio-sensor, for sensing H_2O_2 (detection range 0.1mM to 2.3mM; and detection limit 0.01mM at 3s) in food *via* the reduction of H_2O_2 at pH 5.8 in buffer solution [180]. In 2012, another study was performed related to epinephrine (EP), an important neurotransmitter, using an Au- based GCE electrode with improved sensitivity [181].

Graphene-based nanomaterials also show significant biomedical applications [182]. Various studies have been reported towards the biomedical potential of

graphene such as drug and gene delivery systems, anti-tumor and antibacterial properties with scanning and imaging nature *etc* [183 - 186]. Paramagnetic Fe_2O_3 decorated graphene nanocomposites were applied for magnetic resonance imaging (MRI) and in hyperthermia therapy having improved physiological stability and biocompatibility [187 - 189]. In 2011, Zhang and his co-workers investigated aminodextran-coated Fe_3O_4 graphene nanocomposites for T2-weighted cellular MRI detection having improved T2 relativity *via* the aggregation of Fe_3O_4 nanoparticles on graphene surface (Fig. **13**) [190]. Oleylamine with Ag nanoparticles decorated on graphene oxide surface displayed improved antibacterial property compared to pristine based Ag NPs against Gram-negative bacteria [191]. In 2011, Ma and his co-workers reported the enhanced anti-bacterial activity of Ag-based graphene oxide due to H-bonding between GO and the cell membrane of *E. coli*., which prevents the nutrients uptake from the cell membrane and causes cell death [191].

Catalytic Potential of Graphene-based Nanocomposites

CO Oxidation

CO oxidation is one of the most useful reactions due to its significant potential towards the removal of CO and emission of pollutants [192].

In 2012, Liu and his co-workers synthesized a graphene-based Pd nanocomposite, loaded with 10 wt% Pd on graphitic material which showed the complete conversion of CO at 393 K, and improved stability without significant Pd size change [193]. El-Shall's research group developed bimetallic Pd–CoO based-graphene nanocomposites without using a chemical reductant [194]. They showed that the deoxygenation property of GO and light-induced metallic reduction property can be enhanced during the laser irradiation due to the formation of alloy

structure, which also improved the catalytic property of graphene surface in comparison to the separately deposited graphene surface with Pd or CoO. Similar catalytic performance was also reported for bimetallic Pt–Ni based graphene nanocomposite *via* high dispersion of Pt–Ni on graphene surface [195]. Liu and his co-workers showed that the positively charged Pd-Gr can display a good relation of temperature with CO oxidation (Fig. **14**) [196].

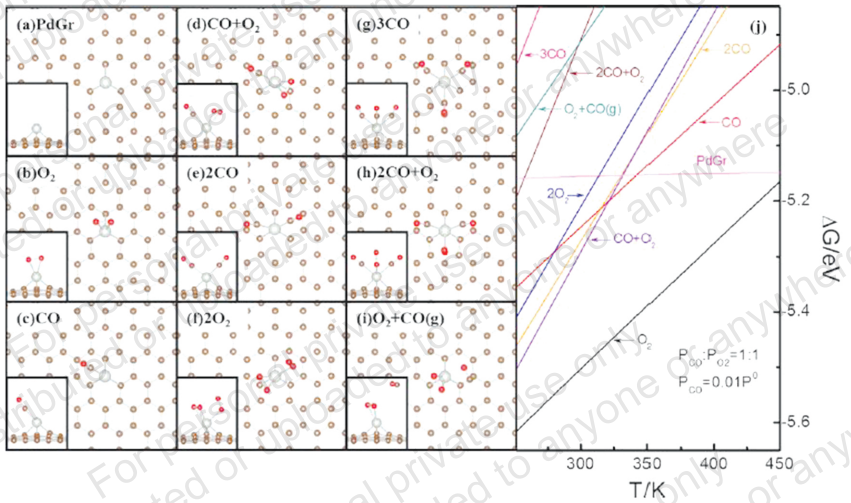

Fig. (14). Left and right-side panels show relation of atomic structures and temperature dependence with Gibbs free energies (ΔG) change over Pd-Gr in CO oxidation. (Reproduced with permission from Ref [196], Copyright 2020, American Chemical Society).

Oxidation of Alcohols

The carbonyl compounds (aldehydes and ketones) are an important group of compounds for the synthesis of several fine chemicals and biologically privileged molecules. The conventional oxidation of alcohol to carbonyl compounds is done by the use of homogeneous transition metal-based catalysts or several organometallic complexes (Fig. **15**). However, these homogeneous catalysts have several potential drawbacks such as moderate to high amount of catalyst loading, difficult removal of catalyst from the reaction medium (due to its toxic nature) and high cost [197]. To overcome these limitations, several research groups demonstrated that the Pd decorated on various carbon based material (like activated carbon [198], CNTs [199], and CMK-3) performed excellent catalytic property for oxidation of benzyl alcohol to benzaldehyde. In this context, graphene was utilized as a support for these transition metals for oxidation of alcohols to carbonyl compounds under a heterogeneous catalytic system.

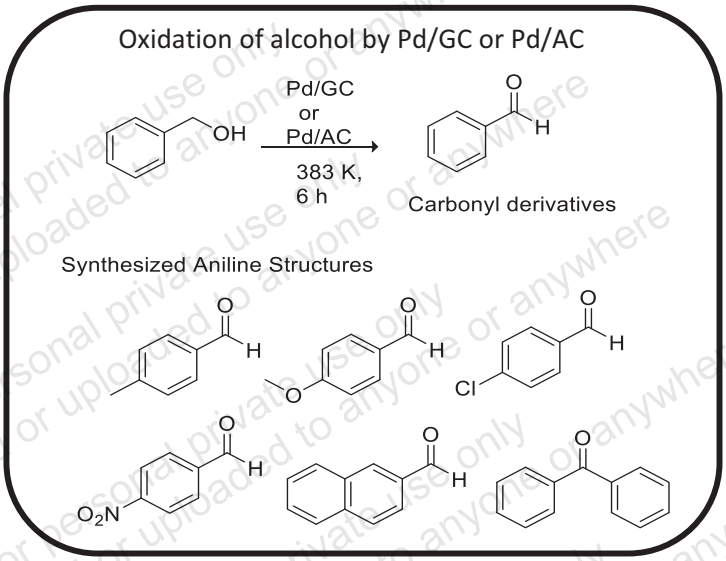

Fig. (15). Benzyl alcohol oxidation by palladium-based nanocomposite on different carbon-based material.

Li and his co-workers synthesized a Pd-based nanocomposite on carbon materials (such as carbon nanotubes, graphene (Pd/G), and activated carbon) *via* impregnation, which showed significant catalytic potential for benzyl alcohol oxidation [200]. The synthesized Pd-based nanocomposites having different carbon materials were approximately of the same size (≈ 4 nm) having the catalytic property in the following decreasing order: Pd/G > Pd/AC > Pd/CNT > commercial Pd/AC.

The observed catalytic activities of nanocomposites were significantly dependent on the use of carbon materials, and graphene was found superior in comparison to the other carbon materials. Huang *et al.* got similar results by decorating Au nanoparticles on several carbon materials, in which the rGO supported nanocomposite displayed the best catalytic performance (selectivity of 93% and conversion rate of 65%) for the oxidation of benzyl alcohol to benzaldehyde [201]. Furthermore, graphene-based metal oxides (eg: NiOx, CoOx, and FeOx,) [202], bimetallic Au–Pd based nanomaterial [203], and magnetically retrievable Fe_3O_4–Pt decorated rGO nanocomposites [204] were also synthesized and utilized for the selective oxidation to carbonyl compounds from alcohols. The bimetallic Au–Pd based graphene nanocomposites were found to be more active in comparison to the others towards selective oxidation to methyl formate from methanol [203].

Graphene-based Nanocomposite for Hydrogenation Reactions

The hydrogenation of various unsaturated organic compounds (such as alkenes, alkynes, nitriles, carbonyl compounds, and nitroarenes) to other privileged compounds is very challenging and has significant industrial applications [205]. In this context, the carbon- based catalytic hydrogenation is one of the most striking pathways due to its several advantages [206, 207] and in recent decades, graphene-based nanocomposites have displayed significant potential in this area.

Selective Reduction of Nitroarenes Using Graphene-based Nanocomposite

Aromatic amines are important precursors utilized for the synthesis of a variety of biologically important materials and industrial chemicals. Selective reduction of nitroarenes *via* catalytic hydrogenation is found to be one of the most effective routes for the synthesis of aromatic amines.

Pd-based nanocomposites display excellent catalytic potential for selective hydrogenation to amines from nitroarenes. In 2014, Wang and his co-workers synthesized graphene-based Pd nanocomposites *via* dispersion on graphene support by a hydrothermal process [206]. Pd-based rGO displayed improved catalytic potential in comparison to the commercial Pd/C towards the synthesis of 4-aminophenol (4-AP) from 4-nitrophenol (4-NP) with a reduction from $NaBH_4$.

Xu and his co-workers discovered similar findings *via* a simple redox reaction of H_2PdCl_4 and GO [208]. In addition, graphene-based Ni-Pd [209] or bimetallic Pd-Cu NPs [210] also displayed efficient catalytic properties towards the hydrogenation of nitroarenes (Fig. **16**).

Ni-Pd based graphene nanocomposites catalyze the tandem reduction of nitroarenes and dehydrogenation of ammonia borane (AB) [209]. Hou and his colleagues synthesized Pt-doped rGO *via* ethylene glycol reduction and used this composite to hydrogenate nitrobenzene *via* H_2 gas [211]. Additionally, it was also found that the hydrogenation efficacy was improved *via* the activation of H_2 gas by using a mixture of Pt and graphene [212]. Fan *et al.* synthesized Ru-decorated rGO nanocomposite *via* a hydrothermal process and utilized this nanocomposite for the selective hydrogenation of halo-nitroarenes [213].

Later on, the same research group also demonstrated higher selectivity of p-CAN over Ru anchored rGO nano-catalyst [214]. Other metal-based nanoparticles such as nickel [215, 216], gold [217, 218], silver [219] and Ni-Co alloy [220], metal oxide nanocomposites like Fe_3O_4 [221] were also anchored on the graphene surface and utilized for selective hydrogenation of aromatic nitro-compounds (Fig. **17**).

Magnetic retrievability and better recyclability are some of the advantageous features for catalysts. In this context, the magnetically separable catalysts were also synthesized by the use of metal NPs such as Pt, Pd, or Pt-Pd on Fe_3O_4/graphene surface, which was functionalized with L-lysine *via* selective doping. The NH_2 and COOH functional groups of L-lysine displayed unique roles as linkers between Fe_3O_4/graphene nanocomposites and the noble metals [222].

Hydrogenation of the C=C Bond using Graphene-based Nanocomposite

Conventionally, the hydrogenation of carbon-carbon unsaturated bonds is performed by metals such as Ru, Rh, Pt, Pd, and Au. In 2013, Maser and his co-workers developed Pd NPs based graphene nanocomposites having improved catalytic properties for the hydrogenation of unsaturated compounds [223].

In another study, graphene-based Pt nanocomposites were also prepared from H_2PtCl_6 having excellent catalytic reductive potential towards reduction of alkenes and alkynes to corresponding alkanes [224]. Han and his co-workers synthesized Ru NPs decorated with rGO for the hydrogenation of toluene [225]. Later on, several other Ru-decorated graphene nano-catalysts were also reported for the reduction of benzene/cyclohexene to cyclohexane [226, 227]. Begin and his co-workers fabricated graphene-based Pd nanocomposites for hydrogenation of cinnamaldehyde *via* H_2 reduction [228]. Furthermore, under microwave irradiated reduction conditions [229] and in solvothermal process [230], graphene anchored-Pd nanocomposites catalyst for the selective hydrogenation of the C=C bond of vinyl acetate and isophorone were reported.

Hydrogenation of the C=O Bond using Graphene-based Nanocomposite

The selective hydrogenation of the C=O bond of α,β-unsaturated carbonyl compounds over C=C bonds is more challenging due to comparably more favorable thermodynamic and kinetic stability of the C=O moiety over C=C bond [231, 232]. In 2014, Fu and his coworkers synthesized graphene-supported Pt nanocomposites for selective hydrogenation of cinnamic aldehyde (CAL) to cinnamyl alcohol (COL) [233]. The authors proposed that the electronic network of graphene based nanocomposite may form the inter-molecular π–π interactions with CAL and the aromatic moiety. Notably, the electron transfer behavior was also found for Pt decorated rGO nanocomposite [234]. The uniform dispersion of Pt on rGO in a specific solvent also displayed enhanced catalytic activity [235]. In addition, Fe [236] and Ni [237] based graphene nanocomposites for C=O over C=C hydrogenation were also reported. Furthermore, chiral-functionalized Ni [238] or Pd [239] nanocomposites based on rGO demonstrated exceptional

catalytic potential for asymmetric hydrogenation, yielding optically pure enantiomers from prochiral substrates. Furthermore, graphene-based Pd [240], Pt [241], and RuO_2 [242] nanocomposites were also reported for selective hydrogenation of cellulose to sorbitol [241], catalytic hydrodesulfurization [240], and selective hydrogenation of carbonyl compounds [242].

Graphene Based Nanocomposite in Fischer–Tropsch Synthesis

CO hydrogenation in Fischer-Tropsch synthesis (FTS) has received a lot of attention [243, 244], and carbon-based materials have been discovered to be good supports for FTS catalysts due to their low interaction with active metals. In this context, a variety of carbon supports (such as carbon spheres, activated carbon, CNTs, mesoporous carbon, and carbon nanofibers) have been utilized for the FTS catalyst synthesis (Fig. **18**) [245 - 247].

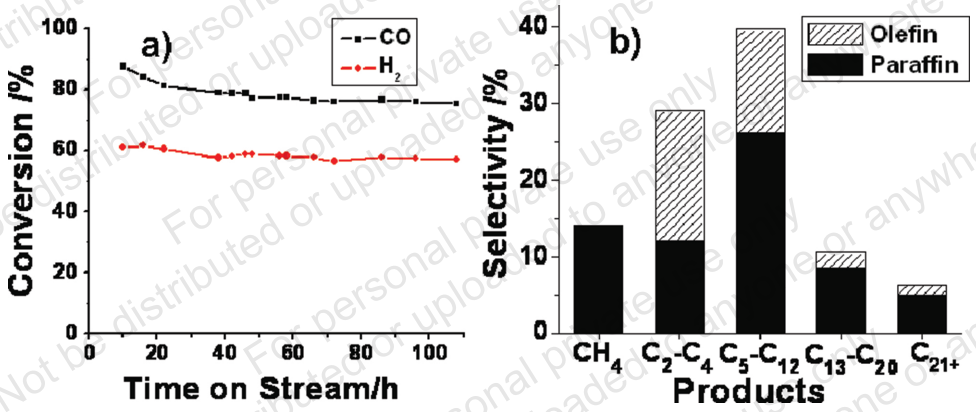

Fig. (18). Fischer–Tropsch synthesis (FTS) on reduced Fe*x*O*y*@C spheres. (**a**) conversion of CO and H_2 with time. (**b**) hydrocarbon selectivity. (Reproduced with permission from Ref [245], Copyright 2010, American Chemical Society).

Qiao and his co-workers synthesized Fe-based rGO nanocomposites *via* hydrothermal hydrolysis and reduction process by the use of GO and $Fe(acac)_3$ [248]. The nanocomposites synthesized demonstrated exceptional catalytic potential as well as thermodynamic stability. From p-rGO, a Fe-anchored pre-reduced GO (p-rGO) was synthesized, which demonstrated improved selectivity and stability to C_{5+} products. This was the first documented report which showed the application of graphene-based nanocomposite having mixed metals at high-temperatures. The role of the oxygen-containing functionalities on graphite support is authenticated over GO decorated with pyrolytic iron in the FTS process [249]. El-Shall and his colleagues created microwave-irradiated graphene-based K/Mn-functionalized iron nano-catalysts [250]. The graphene support improved the C_{8+} products as well as reduced the production of CO_2 and CH_4 as compared to

carbon nanotubes. The synthesis of CO_2 from CO was reduced from 14% to 2.6%. The catalytic selectivity (without CO_2) towards C_{8+} products increased (61.5% to 86.7%), and for CH_4, it was reduced (11.5% to 2.6%). In 2013, Yang and his co-workers fabricated cobalt-based graphene nanocomposites for the hydrogenation of CO_2 *via* a solvothermal process [251]. In the solvothermal process, as the temperature changed from 453 to 493 K, the cobalt nano-catalysts transformed from cubic shape to hexagonal shape, followed by an irregular arrangement to a sea-urchin like structure, and ultimately to a flower like final structure. In CO_2 reduction, the nanocomposites formed at 493 K displayed excellent catalytic properties due to the active hexagonal Co phase formation (Fig. **19**) [252].

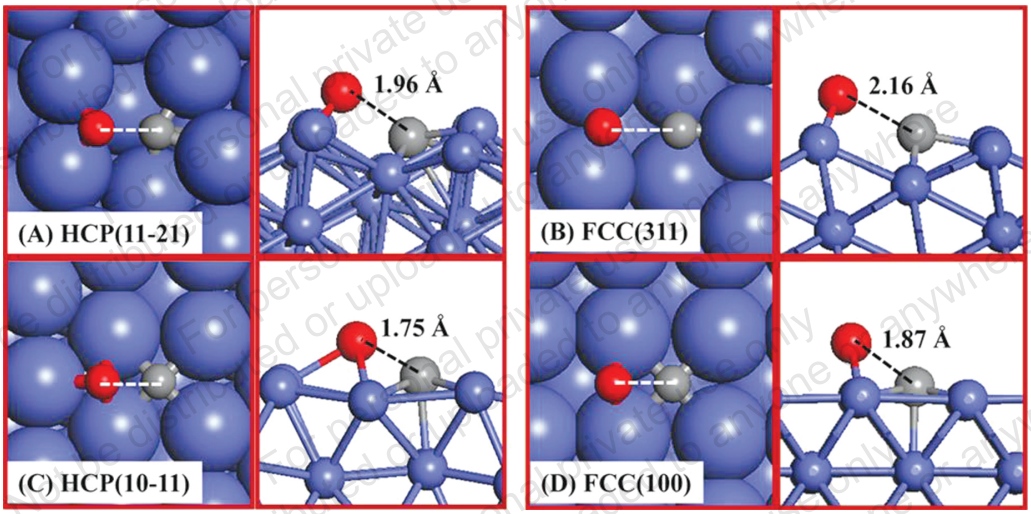

Fig. (19). Top and side views of CO dissociation from optimized TSs. (Blue balls represent Co, red balls represent O, and gray balls represent C atoms). (Reproduced with permission from Ref [252], Copyright 2013, American Chemical Society).

Graphene-supported Nanocomposites for Hydrolysis of AB (Ammonia Borane)

Hydrogen is a well-documented clean fuel due to its safe, efficient delivery and storage point of view [253]. The efficient chemical synthesis of H_2 was performed by using B–N based compounds, in which AB (ammonia borane) was found to be the best one due to its good stability, less hazardous nature, and high hydrogen content (up to 19.6 wt%) [254]. Thus, several research groups have worked towards the synthesis of modified graphene-based nanocomposites having good catalytic potential towards the hydrolysis of AB.

In 2012, Metin *et al.* fabricated Pd-anchored graphene nanocomposites for AB hydrolysis [255]. In the same year, Zeng and his co-workers synthesized Pd-anchored rGO nanocomposite *via* a solvothermal process [256]. Graphene-based

Co [257] and Cu [258] NPs were also developed using AB as a reductant, which displayed improved catalytic properties in comparison to the rGO-free Co or Cu NPs. Similarly, co-anchored rGO [259] and Ru- decorated rGO [260] nanocomposites were also synthesized from methylamine borane (Me-AB) using $NaBH_4$ [260]. Moreover, the bimetallic nanocomposites with graphene support were also fabricated and utilized for the hydrolysis of ammonia borane. Several research groups have fabricated bimetallic graphene-based nanocomposites (like Co-Fe [261], Ni-Co [262], Co-Cu [263], and Ru-Cu [264]. Ciftci and Metin reported Ni-Pd nanocomposites with rGO *via* reduction from $Pd(acac)_2$ and $Ni(OAc)_2$ [265]. Furthermore, other bimetallic graphene-supported nanocomposites such as Cu-Co [266], Ag-Co [267, 268], Pd-Co [269], Ru-Ni [270], and Ru-Co [271], were also synthesized *via* one-step co-reduction employing ammoniaborane as a reductant depending on the change of the two metal substrates in their reduction potentials (Fig. **20**).

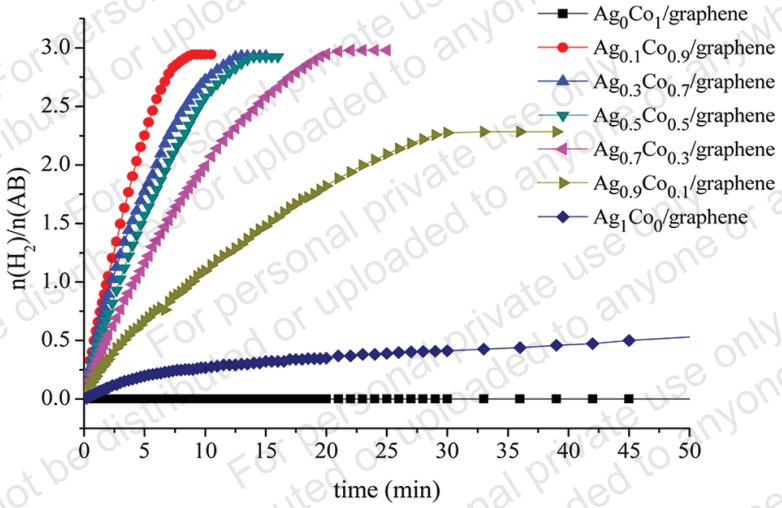

Fig. (20). Representation of H_2 gas generation after hydrolysis from graphene-based nano-catalysts. (Reproduced with permission from Ref [268], Copyright 2013, American Chemical Society).

It is also observed that the graphene-based nanocomposites show improved catalytic nature compared to their graphene-free counterparts. Recent studies have synthesized multi-metallic graphene-based nanocomposite such as Ni-Cu-Co [272], Ni-Ag-Co [273], and Fe-Ag-Co [274] *via* a co-reduction process using NaBH4, Me-AB, or AB as a reductant. In a similar study, it was reported that the catalytic property can be tuned according to the composite size by changing the graphite-based surface of the Ag-Co-Ni nanocomposite for AB hydrolysis [275]. Graphene-based nanocomposites were also utilized for H_2 production from $NaBH_4$ [276], Me-AB [268], and propane [277]. It is noteworthy that the design of

graphene-based nanocomposites was utilized as a key feature for the efficient hydrolysis of AB [278].

Graphene-supported Nanocomposite for Coupling Reactions

C–C bond construction in organic scaffolds *via* coupling reactions is a very demandable approach for both academic research and industrial production. In 2010, the Nobel Prize in Chemistry was awarded to Heck, Negishi, and Suzuki for their potential discovery of Pd-catalyzed cross-coupling reactions. In general, coupling reactions are carried out under homogeneous catalytic conditions; however, due to the severe toxicity profile, poor recovery and recyclability, as well as higher water and air-sensitive properties of homogeneous catalysts, their applications to large scale industrial processes are limited [279]. In this context, reusable heterogeneous catalysts provide potential benefits to overcome this problem.

Typically Pd NPs anchored on some materials like zeolites [280], activated carbon [281], and carbon nanotubes [282] have been utilized for coupling reactions. In recent years, a huge number of graphene-based nanocomposites have been synthesized and utilized for the coupling reactions. In 2009, Mülhaupt and his co-workers developed a Pd-functionalized graphene support by immobilizing the Pd^{2+} on GO *via* cation exchange followed by the reduction from $N_2H_4 \cdot H_2O$, H_2 or thermal reduction (Fig. **21**) [283].

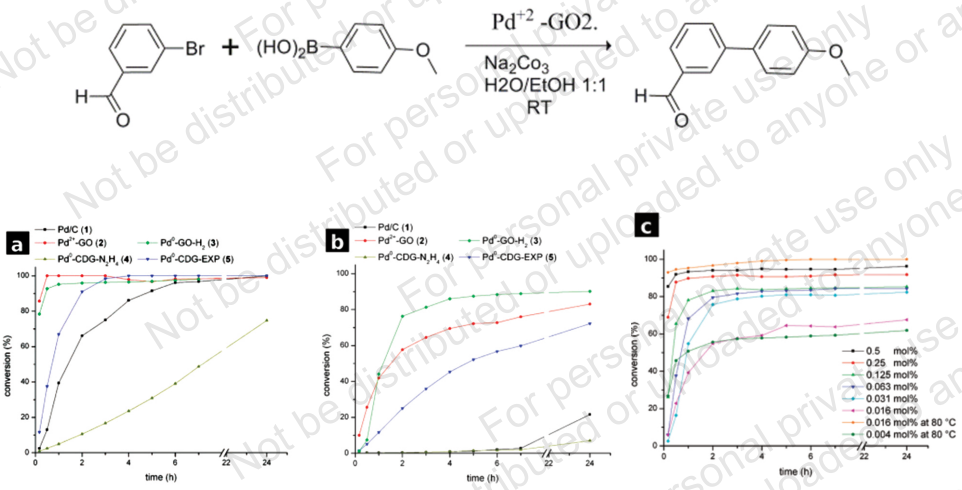

Fig. (21). Screening of Pd-GO/CDG catalysts for Suzuki-Miyaura reaction. Coupling reaction of 4-methoxyphenylboronic acid with (**a**) 4-bromo-1,2-difluorobenzene (**b**) 4-bromo-1,2-(methylenedioxy) benzene (**c**) 3-bromobenzaldehyde. Furthermore, the graphene-based nanocomposites displayed enhanced catalytic activity in comparison to the typical Pd/C catalyst, and very little Pd leaching (<1 ppm) was found. Later on, graphene-based Pd nanocomposites having improved catalytic property were also synthesized with various reductants like H_2 [284], $NaBH_4$ [285], $N_2H_4 \cdot H_2O$ [286, 287], and ascorbic acid [288].

Other approaches were investigated, including CO-reduction with GO and H_2PtCl_6 from Ti^{3+} [289], electrochemical-based CO-deposition [290], thermal exfoliation process [291], and pulsed laser based irradiation [292]. The graphene support based mixed hybrid also demonstrated excellent catalytic properties for Sonogashira and Heck cross-coupling reactions. Notably, it was also documented that the Pd-based graphene nanocomposite displayed improved stability to polymeric materials like polyvinyl pyrrolidone, polystyrene-polyethylene oxide, and poly(amido-amine) dendrimers compared to the Pd nanoparticles (Fig. **22**) [292]. In 2013, Metin and his co-workers developed a synthetic route for graphene-based Ni/Pd nanocomposites *via* a two-step methodology and utilized this synthesized nanocomposite for Suzuki–Miyaura cross-coupling of phenyl iodide and phenylboronic acid [293]. Xu *et al.* developed graphene-supported Pd–Co nanocomposites, which were utilized in the Suzuki coupling reaction of phenylboronic acid with iodobenzene and conversion up to 96% and almost 100% selectivity with respect to biphenyl was achieved [294]. Fan *et al.* developed uniformly deposited Au NPs on graphene support having enhanced catalytic properties compared to unsupported Au NPs by reducing $HAuCl_4$ using sodium dodecyl sulfate [295, 296].

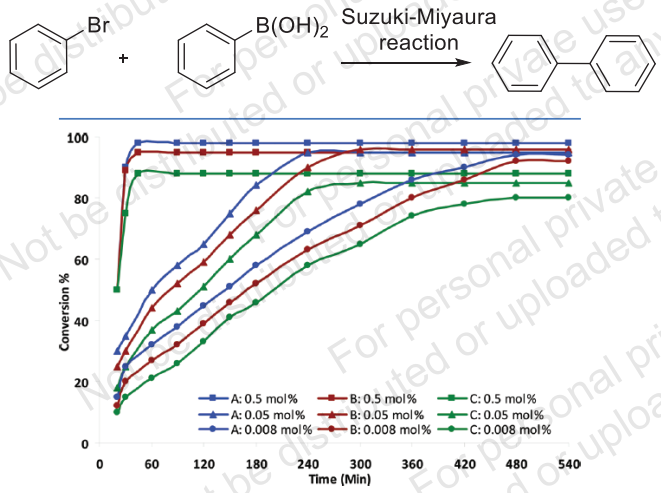

Fig. (22). Pd/PRGO catalytic effect on the conversion of Suzuki reaction. (Reproduced with permission from Ref [292], Copyright 2012, American Chemical Society).

In 2013, Wang and his co-workers investigated a facile synthetic route for Fe_3O_4 doped graphene nanocomposite synthesis *via* thermal decomposition of $Fe(CO)_5$ on GO surface [297]. In 2014, another report was published for graphene-based Ni nanocomposite synthesis and utilization of its catalytic potential in the Kumada-Corriu cross-coupling reaction of 4-iodoanisole and phenyl magnesium chloride. Therefore, the progress of graphene-based nanocomposites with improved catalytic activity and stability towards coupling reactions warrants further research and development.

CONCLUSION AND SUMMARY

Graphene is utilized as a two-dimensional solid support for the growth and nucleation of metal or metal oxide nano-particles, and the synergistic effects of these graphene-supported nanocomposites dramatically enhance the catalytic performance of the composite materials. The better knowledge of graphene surface-based chemistry leads to the development of potential synthetic routes for graphene-based inorganic nanocomposites synthesis by introducing several metal-based NPs. Thus, graphene-based metal nanocomposites with decorated, anchored, doped, encapsulated, layered, wrapped, and mixed structures have demonstrated huge potential for numerous industrial applications and are commercially achievable compared to less active nanocomposites using other carbon family members. The synergistic effects of graphene support and metal NPs in these nanocomposites result in improved catalytic potential in a variety of applications such as medicine, energy, biosensors, and industrial applications. The synthesis of these graphene-based nanocomposites, with well-defined shape and size along with the crystallinity of nanocomposites, not only prevents the restacking of graphene-based nanomaterial but also offers better support for the synthesis of 2D porous materials. This exceptional and remarkable catalytic potential of graphene-based nanocomposite has captured the scientific community's attention enormously, and as a result, a large number of publications and patents related to graphene as well as graphene-based nanocomposite synthesis and utilization have been reported in recent decades. In this context, the recent developments towards the synthesis of graphene-based metal nanocomposites and their catalytic utilization are broadly discussed in the present chapter.

Despite the significant advancement in the preparation of graphene-based nanocomposites, challenges still exist in their catalytic utilization on a large scale. For instance, advanced utilization of graphene-based metal nanocomposites needs further extensive exploration to understand the interactions between metal nanomaterials and the graphene/graphene oxide surface, which have a direct correlation with the catalytic nature of these nanocomposites. A thorough

investigation of these surface interactions will undoubtedly improve the catalytic potential of graphene-based nanocomposites in a variety of fields, including biosensing, drug delivery, imaging, and catalysis. Moreover, the advancement in graphene surface modification will ultimately allow the fabrication of mono/multi-layered nanocomposites and also improve the protocols for the production of graphene-based nanocomposites on a large scale to get an advanced form of nanotechnology to build devices for several potential applications.

LIST OF ABBREVIATIONS

2D structure	Two-dimensional structure
3D composites	Three-dimensional structure
CDG	Chemically derived graphene
CNTs	Carbon nanotubes
DEFCs	Direct ethanol fuel cells
DFAFCs	Direct formic acid fuel cells
DFT	Density functional theory
DMFCs	Direct methanol fuel cell
EDLC	Electric double layer carbon
ERGO	Electrochemically reduced graphene oxide
FLG	Few-layer graphene
GC	Graphene composites
GNP	Graphene nanoparticle
GNS	Graphene nano-sheet
GO	Graphene oxide
HRG	Highly reduced graphene oxide
MWI	Microwave irradiation
OP pesticides	Organophosphorus pesticides
ORR	Oxygen reduction reaction
Pd/AC	Palladium/activated carbon
Pd/PRGO	Pd-partially reduced graphene oxide catalysts
RG/NP	Reduced graphene nanoparticles
r-GO	Reduced graphene oxide

Abstract: The catalytic potential of graphene oxide (GO) and graphite oxide has been well explored in recent years. The reactivity of metal-supported graphite oxide as a solid-phase heterogeneous catalyst has started to be an exceptionally powerful tool for the construction of C-C bonds in synthetic organic chemistry. Among them, palladium has been widely used in different catalysts for a variety of cross-coupling reactions such as Mizoroki-Heck, Suzuki-Miyaura, Kumada, Stille, Negishi, Hiyama, and Buchwald-Hartwig, *etc.*, because of its high catalytic activity and the rapid installation of a complex molecular structure with selectivity in comparison to other transition metal catalysts. A description of recent advances in graphene-supported palladium nanocatalysts for cross-coupling reactions is presented in this chapter. Catalyst synthesis and mechanistic aspects are also given, followed by comparisons with traditional methods.

Keywords: C-C Bond Formation, Cross-coupling Reaction, Graphene Oxide, Graphite Oxide, Reduced Graphene Oxide (r-GO).

INTRODUCTION

Transition metal-catalyzed cross-coupling reactions have emerged as an exceptionally powerful tool for the construction of C-C and C-Hetero atoms bonds in synthetic organic chemistry and continue to have widespread application, especially in drug development programmes and agrochemicals [1, 2]. In the last decades, many transition metals have been employed to carry out cross-coupling reactions. Among them, palladium has been widely used in different catalysts for a variety of cross-coupling reactions such as Mizoroki-Heck, Suzuki-Miyaura, Kumada, Stille, Negishi, Hiyama, Buchwald-Hartwig, *etc.*, because of its high catalytic activity and the rapid installation of complex molecular structure with

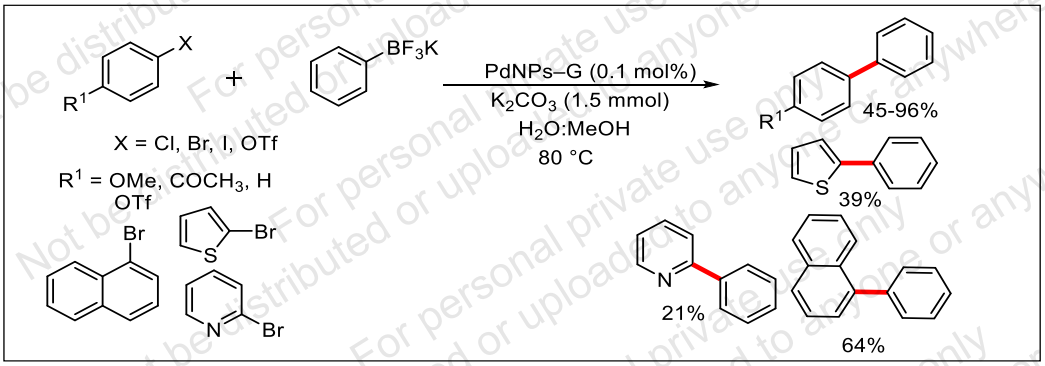
selectivity in comparison to other transition metal catalysts [3]. The impact of palladium-catalyzed reactions in the scientific community has been recognized after getting the Nobel Prize in chemistry by three renowned scientists in this area: Professor Richard F. Heck, Professor Eichi Negishi, and Professor Akira Suzuki [4].

Despite the high impact of homogenous palladium-catalyzed cross-coupling reactions in all fields of science, there are many issues associated with homogenous catalysis, such as the use of a high-cost catalytic system, lack of reusability of catalyst, and potential contamination of the drug by residual heavy metals, which strongly limit their use in the pharmaceutical industry [5, 6]. To address these issues, synthetic chemists started channeling their efforts to innovate environmentally benign processes by developing new catalysts with high efficiency and reusability, applying efficient energy sources, and avoiding the use of ligands and auxiliaries. For these reasons, synthetic chemists moved on to heterogeneous catalysis, in which palladium catalysts immobilized on solid support (organic, inorganic, and hybrid materials) have become an important alternative to address all the issues associated with homogenous catalysis. Several heterogeneous palladium catalysts have been generated using silica [7, 8], zeolites [9, 10], ionic liquids [11 - 13], alumina [14], clay [15], zinc ferrite [16], organic, and inorganic polymers as supports [17 - 22]. There are many carbon-based nanomaterials such as one-dimensional (1D) carbon nanotubes (CNTs), two-dimensional (2D) graphene, amorphous activated carbon (AC), and mesoporous carbon (MC), which have also been applied as supports for the synthesis of palladium nanoparticles catalysts [23 - 26].

Among them, graphene and modified graphene has recently become more attractive support in the field of catalysis and have attracted much attention from the scientific community because of their extraordinary properties. Graphene, a 2D material, is considered a "wonder material" formed by carbon atoms that are arranged in a hexagonal monolayer pattern (a honeycomb crystal lattice). Each carbon atom of graphene is sp^2 hybridized and 200 times harder than steel, very feathery, and flexible [27 - 29]. In addition, graphene possesses a large surface area, and excellent chemical, thermal and electrical stability. Moreover, it showed a strong hydrophobic interaction with metal and was easily modified to other forms [30]. Graphene-based architectures are highly desirable in the synthesis of metal nanoparticles, especially as a support for palladium nanoparticles (PdNPs), and displayed exceptional catalytic efficiency for C-C cross-coupling reactions because graphene has high binding energy with palladium and good charge storage performance [31]. Moreover, due to the presence of transparency and conductive properties of graphene it also plays a vital role in the areas of electrochemical applications such as sensors [32], electrodes [33], and fuel cells

[34]. Furthermore, graphene derivatives, such as graphene oxide (GO) and reduced graphene oxide (rGO) have also become useful support in nano metal-catalysis due to their structural defects, which allow an easy covalent and non-covalent (hydrogen-binding or π-stacking) functionalization of the material that can be used either as supports for immobilizing active species or as metal-free catalysts and enhancing the rate of interaction with anchored metal nanoparticles [35, 36]. Graphene oxide was first synthesized by oxidation of graphite in acidic conditions using the Hummers-Offeman method [37]. This method involves the treatment of graphite with sodium nitrite ($NaNO_3$), potassium permanganate ($KMnO_4$), and followed by hydrogen peroxide (H_2O_2).

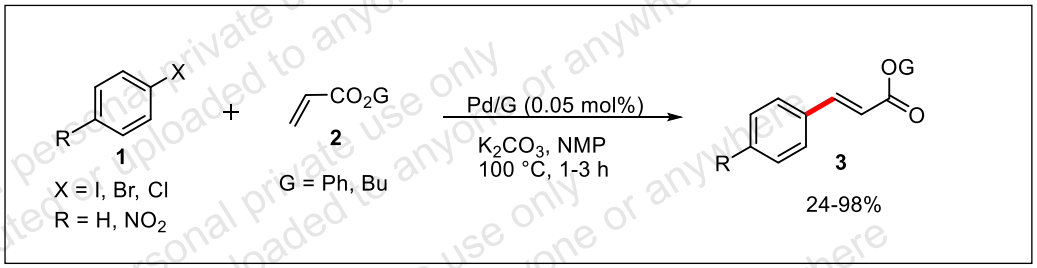


Recently, Palladium nanoparticles (PdNPs) have established as an intensively investigated and rapidly growing area in ligand-free catalysis because of their high surface-to-volume ratio and highly active surface atoms in comparison to other bulk catalysts [38 - 42]. Palladium nanoparticles (PdNPs), used as a heterogeneous catalyst for the production of pharmaceutical agents, herbicides, fine chemicals, and polymers have a lot of advantages over the palladium-catalyzed homogenous reactions because of their remarkable features such as stability, selectivity, reusability, cost-effective, simple workup procedure and easy separation of the final product [43]. Palladium nanoparticles (PdNPs) supported on graphene/graphene oxide (GO) /reduced graphene oxide (rGO) increase the surface area of nanohybrids by expanding the distance between the sheets. This process enhances the catalytic performance of this type of heterogeneous catalyst. These heterogeneous catalysts have not only shown their catalytic efficiency for catalyzing the cross-coupling reactions in which carbon-carbon bond is formed but they have also been applied in other reactions, such as hydrogenation of alkenes, alkynes, and hydrogenation of carbonyl (-CO) and nitro ($-NO_2$) groups [44 - 52].

This chapter covers the graphene/graphene oxide (GO)/reduced graphene oxide (rGO) supported metal nanoparticles catalyzed cross-coupling reactions such as Suzuki, Heck, and Sonogashira, leading to the formation of biological importance molecules.

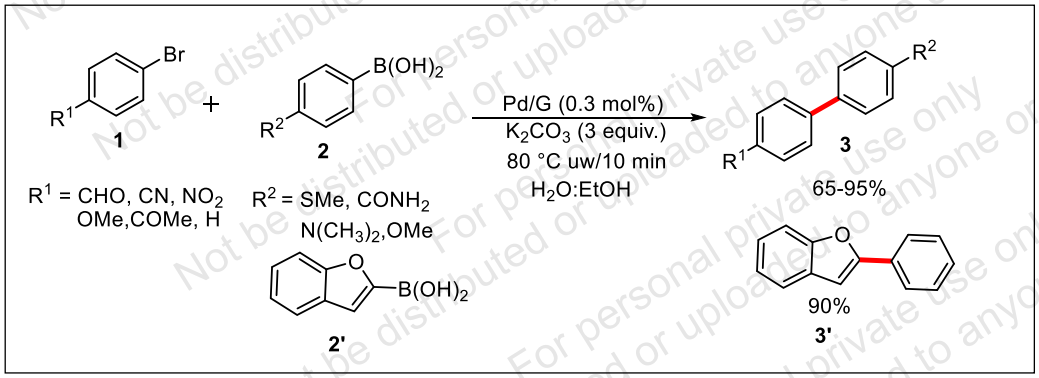
GRAPHENE SUPPORTED PALLADIUM NANOPARTICLES (PDNPS/G) CATALYZED CROSS-COUPLING REACTIONS

Palladium nanoparticles supported on graphene (PdNPs-G) and reduced graphene oxide (PdNPs-rGO) have been used as catalysts for Suzuki cross-coupling reactions between aryl bromides and potassium aryltrifluoroborates by Gómez-Martínez and his co-workers in 2015 [53]. Potassium aryl- and heteroaryl-trifluoroborates efficiently coupled with various aryl halides in the presence of 0.1



mol% catalyst, potassium carbonate as a base in MeOH:H_2O as solvent using conventional and microwave heating to generate a library of functionalized biphenyl derivatives in good to excellent yields (Scheme **1**). Sterically hindered substrate such as 2-bromo-1,3-dimethylbenzene was unable to provide the cross-coupling product in good yield with potassium phenyltrifluoroborate. Heterocyclic bromides such as 2-bromopyridine and 2-bromothiophene were smoothly coupled with potassium phenyltrifluoroborate to give the coupling products with slightly lower yields. However, less reactive chlorobenzene gave the lowest yield of coupling products. Microwave irradiation provides a lower accumulation of the PdNPs. Identical results of coupling products in terms of yields have been observed using microwave and conventional heating. It is interesting to note that this catalyst was used in Gram-scale synthesis and provides an excellent yield of Suzuki products without loss of catalytic activity. The reusability of the catalyst was also studied and found that the catalyst could be reused up to eight times without loss of significant activity under microwave irradiation, whereas four times when the conventional heating condition was applied.

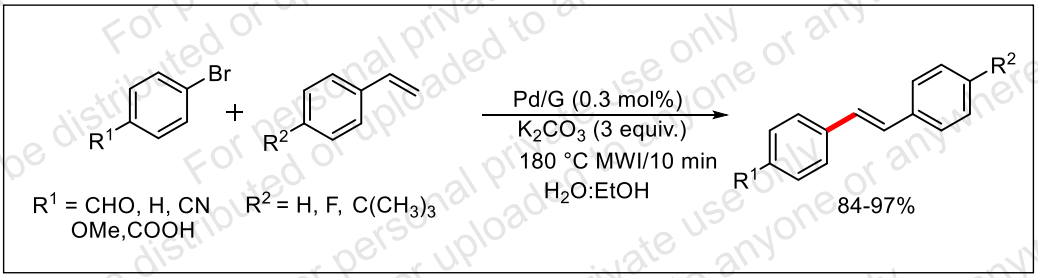
Scheme (1). Synthesis of biaryl derivatives using PdNPs-G catalyst.



Wang and co-workers disclosed the formation of graphene-supported Pd (Pd/graphene) catalyst derived from graphene oxide (GO) and $PdCl_2$ followed by reduction with hydrazine hydrate in an aqueous medium [54]. The performance of this catalyst was investigated in Heck cross-coupling reactions in which iodo- and bromobenzene efficiently coupled with *n*-butyl acrylate or styrene in the presence of 0.05 mol% Pd/G and K_2CO_3 as the base at 100 ^{0}C to provide the coupling products in good to excellent yields (Scheme **2**). However, chlorobenzene was unable to provide a satisfactory coupling product even after increasing the catalyst loading and reaction time. The reusability of the catalyst was also studied using the reaction between bromobenzene with *n*-butyl acrylate. The recycled catalyst could be used seven times without significant loss of activity. Pd NPs in

Pd/graphene were uniformly dispersed on the surface of graphene as displayed by the TEM image. The shape and size of Palladium nanoparticles were found to be spherical and ranged from 2-6, respectively.

Scheme (2). Heck cross-coupling reaction catalyzed by Pd/G catalyst.

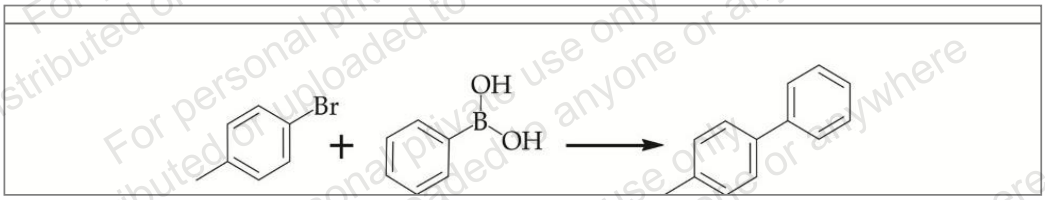


Siamaki *et al*. described a highly efficient protocol for the formation of graphene supported-palladium nanoparticles; in which an aqueous mixture of Pd $(NO_3)_2$ and GO sheets were reduced under microwave irradiation in the presence or absence of hydrazine hydrate respectively [55]. The catalytic exploration of these Pd/G and Pd/GO catalysts was tested using C-C cross-coupling reactions (Suzuki and Heck) without the use of any ligand in aqueous ethanol. The author observed that both catalysts (Pd/G and Pd/GO) exhibit excellent catalytic activity towards the cross-coupling reaction of phenylboronic acid with aryl halides (Scheme **3**), however, Pd/G displayed outstanding activity towards the Suzuki coupling even at low concentrations.

Scheme (3). Graphene-supported palladium catalyzed Suzuki reaction.

The Pd/G catalyst promotes the coupling reaction between bromobenzene and phenylboronic acid with a very low catalyst loading (0.007 mol% Pd/G) to form a biphenyl derivative with a TON of 9000, a TOF of 108 000 h^{-1}, and a 63%

conversion at 80 °C under microwave for 5 min radiation. It is interesting to note that this is the highest TOF for palladium-catalyzed Suzuki cross-coupling reaction under microwave irradiation. Pd/G catalyst also showed excellent catalytic activity towards the Heck cross-coupling. Many aryl bromides coupled with a variety of olefins in the presence of 0.3 mol% of Pd/G, K_2CO_3 as a base in H_2O:EtOH at 180 °C under microwave irradiation. Aryl bromides bearing electron-donating or electron-donating groups easily react with olefins even with inactivated olefins such as *tert*-butylstyrene to furnish excellent yield of the coupling products (Scheme **4**). The recyclability of the catalyst was also examined and found it could be reused eight times without loss of catalytic activity. The activity of the catalyst was dropped after eight times due to the agglomeration and accumulation of the Pd nanoparticles on the surface of graphene. The uniform dispersion of Pd nanoparticles on both graphene and graphene oxide was confirmed by TEM images. The size of NPs supported on graphene was found to be smaller than those supported on the GO sheets.

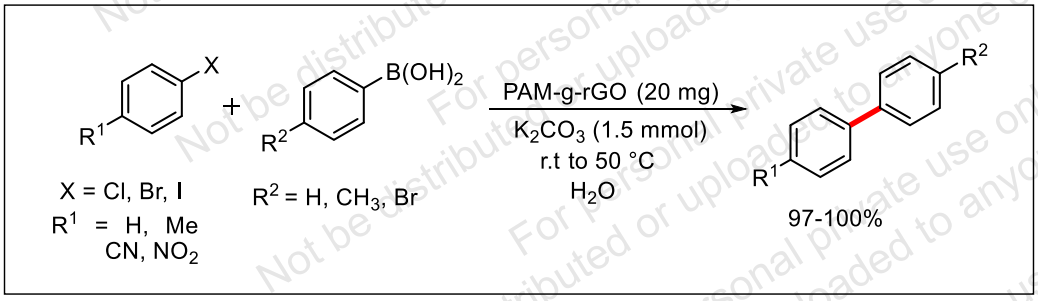


Scheme (4). Pd/G catalyzed Heck cross-coupling reactions.

Later, Gilliland III *et al*. research group developed the catalysts having several defect sites through strong electrostatic adsorption (SEA) with solvent-free microwave reduction method using four different types of commercially available graphene supports (graphene powder 1-5 layers, graphene oxide, reduced graphene oxide, and graphene Nanoplatelet aggregates) as starting materials [56]. The synthesized catalysts were characterized using different analytical techniques such as powder x-ray diffraction (XRD), transmission electron microscopy (TEM), and X-ray photoelectron spectroscopy (XPS). The prepared catalysts (graphene Nanoplatelet) were economical and showed excellent activity towards the Suzuki cross-coupling reactions than other graphene-based supports (Scheme **5**).

In 2013, Lee and co-workers demonstrated a multistep route for the synthesis of a high-performance graphene-based palladium nanoparticles catalyst and evaluated their catalytic power towards the copper and ligand-free Sonogashira reaction

[57]. The synthetic route involved the formation of multilayer Pd^{+2}/GO intermediate between the reaction of GO with $Pd(OAc)_2$ followed by reduction and exfoliation into Pd/G using H_2 gas as a reducing agent. TEM images displayed the uniform distribution of PdNPs on the surface of graphene sheets without aggregation. The mean particle size of PdNPs was found to be 1.4 ±0.6 nm with the help of ICP-MS. The synthesized catalyst exhibited excellent catalytic activity in the Sonogashira coupling reaction in which iodobenzene coupled with phenylacetate in the presence of the formed catalyst (Pd/G) without using any ligand to form biphenylacetylene derivative in a high (89%) yield. There are many advantages of this catalyst such as easy removal of catalyst from the reaction mixture and reusability; *i.e.* it can be reused five times without loss of significant activity.

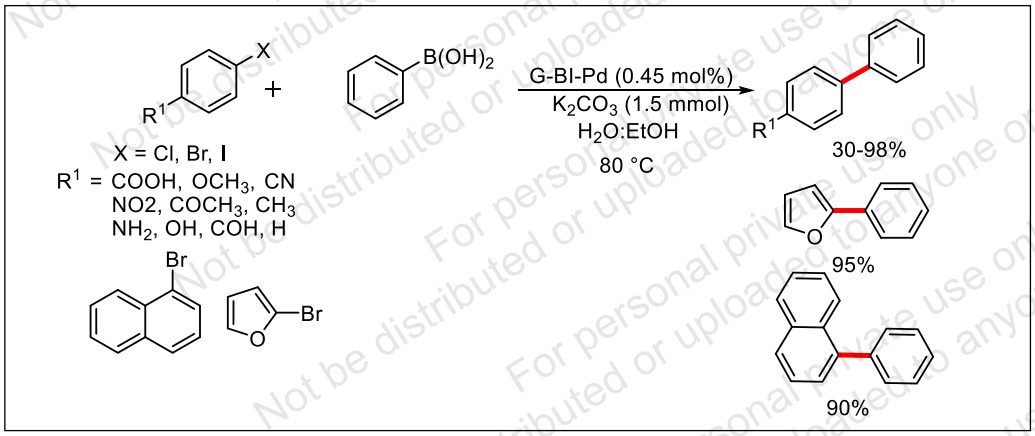


Scheme (5). Suzuki cross-coupling.

In 2015, Rana research groups fabricated a new type of nanocomposite catalyst by highly deposited PdNPs on organodiamine-functionalized graphene support. Organodiamine-functionalized graphene was synthesized by the reaction of [3-(--Aminoethylamino)propyl] trimethoxysilane (AAPTMS) with GO using toluene as solvent. Organodiamine-functionalized graphene-supported PdNPs were obtained by a reduction of $Pd(NO_3)_2$ using $NaBH_4$ as a reducing agent [58].

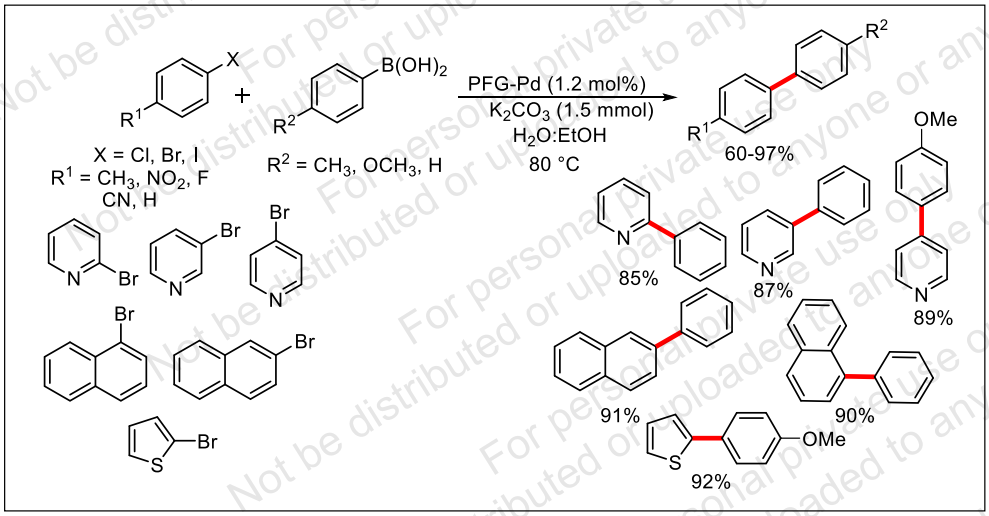
Organodiamine-functionalized graphene support worked as a stabilizer for Pd NPs and provides sufficient electron density to Pd(0) during oxidative addition of aryl halide. In addition, it also worked as excellent support that helped in eluding "Ostwald ripening". The newly fabricated catalyst exhibited outstanding activity toward the Suzuki cross-coupling reaction of aryl iodides with phenylboronic acids. The reaction was performed in the presence of 0.05 mol% of catalyst using $Ba(OH)_2$ or K_3PO_4 as a base in an aqueous medium providing 98% yield with 100% conversion of starting materials (aryl iodides with phenylboronic acids). 2-bromopyridine smoothly reacted with phenylboronic acid producing biaryl products in good yield, whereas chlorobenzene was unable to provide the desired products. The authors proposed the reaction mechanism in which oxidative addition of phenyl halide in the presence of a catalyst is the main step. The yield of coupling products was not increased when catalyst loading was increased from 0.05 mol% to 0.06 mol%. The catalyst was recycled up to six times without any

change in catalytic activity. However, noticeable changes can be seen in the catalytic activity of the catalyst after the seventh and eighth repetitive uses in cross-coupling reaction, the leached amount of Pd was ~10% and ~15% respectively, which indicated that the redeposition of the Pd species was not fully completed during the release-redeposition cycle. TEM images displayed that Pd nanoparticles (3-7 nm) were uniformly distributed on the surface of amine functionalized graphene.



Mahdavi *et al*. employed a similar strategy for the development of polyacrylamide (PAM) functionalized Graphene oxide supported palladium nanoparticles (PAM-g-rGO/Pd) catalyst using ammonium cerium (IV) sulphate $[(NH_4)_4Ce(SO_4)_4 \cdot 2H_2O]$ induced by redox polymerization [59]. PAM helps to make effective dispersion of graphene oxide because of its high polarity and hydrophilic nature. Then PdNPs were synthesized on the surface of PAM-g-rGO using $NaBH_4$ as a reducing agent. The synthesized catalyst was used for Suzuki cross-coupling reactions to observe its catalytic activity. The reactions were performed between different aryl halides and boronic acid in the presence of PAM-g-rGO/Pd using potassium carbonate as a base in an aqueous medium. Iodobenzene-bearing electron-withdrawing substituents efficiently coupled with boronic acid to furnish the corresponding biphenyl products in 100% yields. However, bromobenzene and chlorobenzene needed a long reaction time to couple with the boronic acid and provide the coupling products in excellent yields. Boronic acid that incorporated electron-donating substituents smoothly reacted with aryl halides to provide the corresponding products in excellent yield except methyl boronic acid gave 100% yield of coupling product with iodobenzene. The most important thing about this type of heterogeneous catalyst is its reusability. The catalyst can be recycled successfully up to eight times with a minimum loss of activity (Scheme **6**).

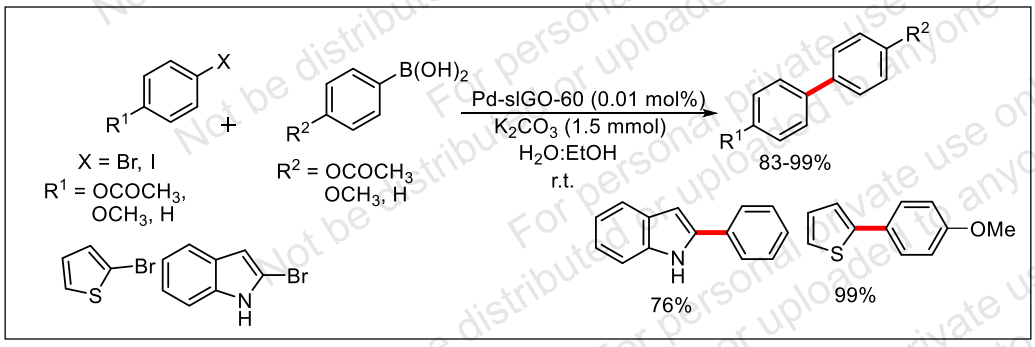
Scheme (6). Suzuki cross-coupling reaction catalyzed by PAM-g-rGO/Pd.



Another important approach has been described for the synthesis of reusable heterogeneous catalysts based on palladium nanoparticles supported on graphene-

benzimidazole(G-BI-Pd) by Sarvestani and co-workers [60]. The catalyst was prepared in the following steps. In the first step, graphene oxide-benzimidazole was prepared by the reaction of graphene oxide with an excess amount of *ortho*-phenylenediamine in the presence of polyphosphoric acid which subsequently underwent reduction of graphene oxide using hydrazine as a reducing agent to generate benzimidazole-grafted graphene (G-BI). Finally, PdNPs were immobilized on the surface of benzimidazole-grafted graphene to form (G-BI-Pd) *via* the formation of the N-Pd complex. Several analytical techniques have been used for the confirmation of synthesized catalysts. The developed catalyst demonstrated superb catalytic activity toward the Suzuki cross-coupling reaction of aryl halides with phenylboronic acids (Scheme **7**). The best results were obtained in terms of yield when the reaction was performed in the presence of 0.45 mol% of G-BI-Pd catalyst using potassium carbonate as a base in an aqueous medium at 80 ^{0}C. Bromobenzene/iodobenzene having electron-withdrawing or electron-donating substituents smoothly transformed into the corresponding biphenyl products in short reaction times with excellent yields. Aryl bromide required a longer reaction time to complete the reaction in comparison to iodobenzene. 2-bromofuran and α-bromo-naphthalene were smoothly converted into the corresponding products in excellent yields under the same catalytic system, except for chlorobenzene which was unable to provide good results in terms of yields. This heterogeneous catalyst showed high stability and could be reused up to five times without loss of their catalytic activity. The uniform distribution of palladium nanoparticles on the surface of G-BI and no aggregation was observed in TEM images.

Scheme (7). Synthesis of biphenyl derivative using GBIPd catalyst.



In continuation, Fareghi-Alamdari and co-workers also applied a similar strategy for the construction of palladium nanoparticles catalyst decorated on the surface of phosphine functionalized graphene (PFG-Pd) and demonstrated its application as a highly efficient catalyst for the Suzuki cross-coupling reaction [61]. A phosphine functionalized graphene (PFG) was prepared by the treatment of graphene oxide (GO) with potassium hydroxide resulting in the formation of a free hydroxyl group on the surface of graphene (GOH). The generated hydroxy-functionalized graphene reacted with chlorodiphenylphosphine ($ClPPh_2$) to form phosphine grafted graphene oxide $GOPPh_2$ (PFG), which could be helpful in the preparation of reusable metal catalysts and for the stabilization of metal nanoparticles or the complexation of transition metals. The application of phosphine functionalized graphene (PFG-Pd) catalyst was tested for Suzuki cross-coupling reaction and found that different aryl halides bearing electron-donating or electron-withdrawing substituents smoothly reacted with arylboronic acids using 1.2 mol% of PFG-Pd catalyst and K_2CO_3 as a base in aqueous medium at 80 ^{0}C providing the corresponding biphenyl products in good to excellent yields. Heterocyclic substrates were also applied in place of aryl halides which smoothly coupled with arylboronic acid to furnish the coupling products in good to excellent yields but with more reaction time (Scheme **8**). It is interesting to note that this catalyst was also used for Heck cross-coupling and *N*-arylation. The catalyst can be consecutively recycled up to five times without significant leaching of the palladium catalyst.

Scheme (8). Synthesis of biaryl derivatives using Suzuki cross-coupling reaction.

GRAPHENE OXIDE (GO) SUPPORTED PALLADIUM NANOPARTICLES (PDNPS/GO) CATALYZED CROSS-COUPLING REACTIONS

In 2014, Yamamoto and his research group described the synthesis of palladium nanoparticles supported on single layer oxide (Pd-slGO) using palladium (II) acetate ($Pd(OAc)_2$) and GO using ethanol as solvent [36]. Ethanol also acted as a reducing agent for palladium precursor at room temperature or 60 ^{0}C or 100 ^{0}C. TEM images displayed that Pd-slGO-60 (reaction at 60 ^{0}C) had a smaller particle size in comparison to PdslGO-100 (reaction at 100 ^{0}C), whereas Pd-slGO-r.t (reaction at room temperature) was not exit at room temperature. Pd-slGO-60 exhibited outstanding catalytic activity towards the Suzuki cross-coupling reaction between iodobenzenes/bromobenzenes with phenylboronic acids. Bromobenzene-bearing electron-withdrawing groups efficiently coupled with phenylboronic acids in the presence of 0.01 mol% of catalyst (Pd-slGO-60) using K_2CO_3 as a base in EtOH:H_2O at room temperature to furnish the corresponding biaryl products in moderate to excellent yields whereas bromobenzene with electron-donating substituents was less reactive towards the phenylboronic acids (Scheme **9**). However, heterocyclic bromides, such as thienyl bromide and indolyl bromide were easily transformed into the corresponding coupling products with phenylboronic acids using the same catalyst. It is interesting to note that iodobenzene showed much reactive towards the phenylboronic acid to provide the coupling product in good yield using 0.00016 mol% catalyst with a turnover number (TON) and TOF (h^{-1}) of 237 000. Moreover, the authors also proved that GO could be used as a scavenger to prevent Pd leaching and contamination of the product. The reusability of this catalyst was also investigated and found that the catalytic activity was dropped after three runs due to the aggregation of PdNPs on the surface of GO and reduction in particle size.

Scheme (9). Synthesis of the biaryl derivative using Pd-slGO-60 catalyst.

In recent years, three-dimensional graphene-based materials (3DGMs) have become an emerging support for the synthesis of heterogeneous nano-catalysts because of their high surface area, low mass density, mechanical strength, and flexible porosity [62]. The remarkable feature of this type of heterogeneous catalyst is its porous structure, which could be used in the stabilization of metal nanoparticles and control their growth [63, 64].

In 2017, Tran and co-workers have discovered a novel method for the preparation of palladium nanoparticles catalyst supported on graphene oxide framework (Pd@GOF) [65]. According to this approach, graphene oxide was first intercalated with benzene-1,4-diboronic through a covalent bond to achieve a three-dimensional (3D) structure. After that PdNPs were formed by the reduction of $PdCl_2$. The intercalation of graphene oxide (GO) with benzene-1,4-diboronic acid through a covalent link afforded a three-dimensional GOF structure having uniformly expanded interlayer spacing which provided thermal stability. The fabricated palladium nanoparticles were uniformly encapsulated and stabilized inside the rigid framework. The synthesized catalyst (Pd@GOF) was used for Suzuki's cross-coupling reaction of aryl halides with phenylboronic acids to evaluate its catalytic performance and found that it exhibits superb activity in both polar and non-polar solvents in terms of yields and could be recycled at least five times without significant loss of catalytic activity.

Functionalized graphene oxide-based materials have been considered as promising supports for nanoparticles and play a significant role in organic transformations such as C-C bond forming cross-coupling reactions [66]. The functional groups present in graphene oxide make the sorption and intercalation of ions and molecules possible and are very helpful in making promising materials for catalytic applications [67]. In 2014, a recyclable heterogeneous catalyst based on palladium nanoparticles supported on non-covalently functionalized graphene oxide (GO) using 1-pyrene carboxylic acid has been developed by Sharavath and Ghosh [68]. Graphene oxide was reacted with a 1-pyrene carboxylic acid in the presence of sodium hydroxide and hydrazine monohydrate to form functionalized graphene and was dispersed in ethanol for 30 min. After that, $PdCl_2$ was added to the above suspension which reduced to palladium nanoparticles (PdNPs). It is interesting to note that ethanol worked both as a solvent and as a reducing agent. The fabricated catalyst (PCA-GNS-Pd) was found to be effective in the promotion of the Suzuki cross-coupling reaction between aryl halides and phenylboronic acids in an aqueous medium. Aryl bromide-bearing electron-donating and electron-withdrawing substituents are easily coupled with phenylboronic acids to transform into the corresponding biphenyl products in good yields. The synthesized catalyst was also useful for unreactive substrates such as chlorobenzene, which reacted smoothly with arylboronic acids to provide

coupling products in good yields (see Table **1**). The application of the PCA-GN--Pd catalyst was further demonstrated for the Heck cross-coupling reaction of aryl halides and olefins. A series of Heck coupling products were obtained in good yields using 0.2 mol% of nanocatalyst in water.

Table 1. Synthesis of biaryl analogous *via* Suzuki cross-coupling of aryl halides with phenylboronic acid using PCA-GNS-Pd catalyst[a].

Entry	R^1	X	Yield (%)[b]	Time (h)
1	H	Br	97	2

[a]Reaction conditions:aryl halide (1.435 mmol), phenylboronic acid (1.722 mmol) Na_2CO_3 (2.153 mmol), water (5 mL), PCA-GNS-Pd (3 mg, 0.2 mol %) (mol% Pd *vs.* halide), heated to 90 °C. [b]Isolated yield. [c]PCA-GNS-Pd (3 mg, 0.6 mol% Pd *vs.* halide) was used. [d]Isolated yield and time using Et_3N as base. [e]4-Cyanophenylboronic acid was used instead of $PhB(OH)_2$. [f]2-Napthylboronic acid was used instead of $PhB(OH)_2$.

The nanocatalyst was recovered and successfully reused up to five times without loss of catalytic performance. The catalytic efficiency of the catalyst was dropped after the fifth run due to the leaching of PdNPs from the support during the reaction and their agglomeration on the catalyst support, which was analyzed by ICP-AES.

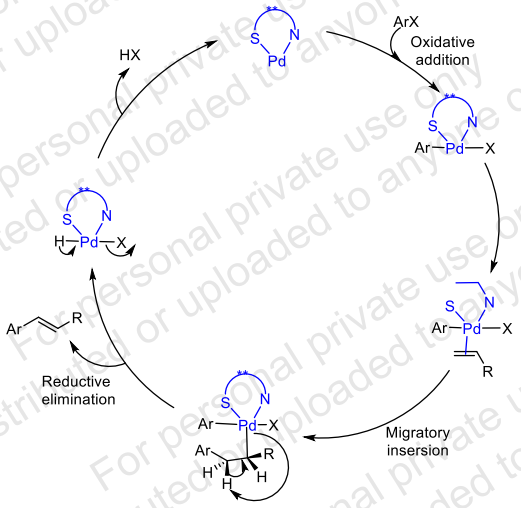
Very recently, Mohazzab's research group has developed a novel and efficient method for the fabrication of separable palladium nanoparticles (PdNPs) supported on graphene oxide (GO)/stainless-steel mesh using a laser ablation in liquids (LAL) process and an electrophoretic deposition (EPD) technique [69]. In this method, no need of any chemical or capping agents was required during the preparation of a mesh-GO/Pd catalyst. The developed catalyst was characterized by using various analytical techniques. The catalytic performance of this catalyst was investigated for Suzuki cross-coupling reaction in ethanol-water without the use of any ligand. The results showed that aryl halides having either electron-attracting or electron-releasing groups smoothly coupled with phenylboronic acids and provided coupling products in excellent yields. In addition, less reactive chlorobenzene also reacted with phenylboronic acids affording the corresponding products in good yields. The reusability of this catalyst was also examined using the Suzuki cross-coupling reaction and found that it could be recycled up to five times with no remarkable loss of catalytic activity.

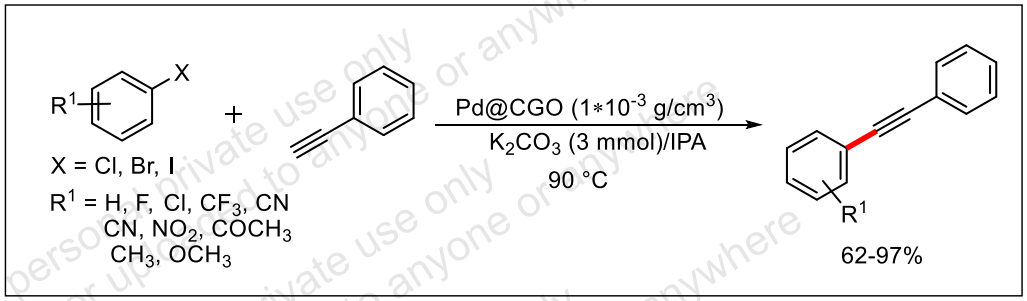


The research group of Premia has described another method for the functionalization of graphene oxide with heteroatoms such as sulfur and nitrogen on which Palladium nanoparticles (PdNPs) were uniformly dispersed [70]. The presence of functional groups in graphene oxide can increase the rate of dispersion of nanohybrids in organic solvents and can be used as a ligand to stabilize the active palladium species. The fabricated catalyst was applied for the Heck cross-coupling reaction to prove its catalytic performance. The coupling reactions between aryl iodides/bromides and substituted styrenes/acrylates were performed in the presence of 0.02 mol% of catalyst using potassium hydroxide as a base at 120 ^{0}C in DMF-H_2O (Scheme **10**).

Scheme (10). GL-Pd catalyzed Heck coupling between aryl halides and olefins.

Under the catalytic system, aryl halides bearing electron-withdrawing groups reacted smoothly with olefins to give the corresponding stilbene derivatives,

whereas lower yields of coupling products were obtained with aryl halide bearing electron-donating substituents. Heteroaryl halides such as 2-bromo-pyridine are also easily coupled with styrene to afford the corresponding coupling products in moderate yields. In addition, polycyclic aryl halide was also used to increase the scope and versatility of the reaction. As shown in Scheme (**11**), the proposed reaction mechanism for the Heck cross-coupling reaction was initiated by the formation of GL-Pd complex I in which Pd is stabilized through coordination with sulfur and nitrogen. Then, aryl halide was activated through oxidative addition with Pd(0) to form complex II followed by the coordination of olefin to give π-complex III and then migratory insertion of olefin takes place to generate IV. Subsequently, *β*-hydride elimination takes place to afford coupling product with the regeneration of the catalyst. The nano-catalyst was recovered, and reused up to three times without any significant loss of its catalytic efficiency, but catalytic activity was dropped after the third cycle due to the aggregation of PdNPs.

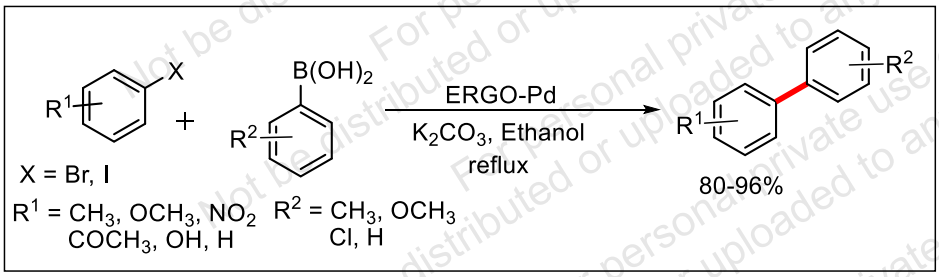


Scheme (11). Proposed mechanism for the Heck coupling reaction.

Recently, Veisi and co-workers reported the synthesis of palladium nanoparticles supported on the surface of graphene oxide, functionalized with metformin (MET) [71]. Metformin functionalized graphene oxide (Met-GO) was prepared between the condensation reaction of graphene oxide with metformin and then palladium nanoparticles (PdNPs) were decorated onto the surface of functionalized graphene oxide by the reduction of $PdCl_2$ using hydrazine hydrate as reducing agents. TEM and FESEM images showed that palladium nanoparticles were uniformly incorporated onto the surface of functionalized graphene oxide. The synthesized catalyst showed outstanding catalytic performance towards the Heck cross-coupling reaction of various aryl halides with olefins without the use of any

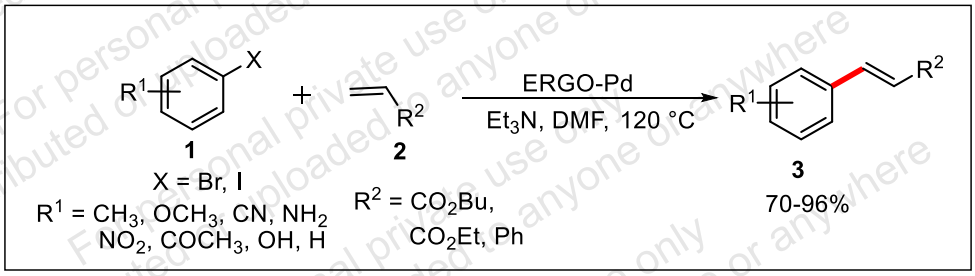
phosphine or ligand coordination. The coupling reaction proceeded in good to excellent yields of trans-stilbene derivatives between the reactions of aryl halides with olefins using 0.1 mol% of catalyst, triethylamine as a base in DMF at 120 ^{0}C. The catalyst was found to be the most effective in the Gram-scale synthesis of trans-stilbene product. The most impressive feature of this catalyst was its reusability, and it could be recycled up to seven cycles without a noticeable loss of its catalytic performance. A hot filtration test was carried out to determine the heterogeneity of this synthesized catalyst (Met-GO-Pd) using Heck cross-coupling reaction between aryl bromide and styrene under optimized reaction conditions. Then, coupling products were obtained in 54% yield and the catalyst was separated out. After separating the catalyst, the reaction was continued for another hour. However, no significant improvement was observed in the yield of the coupling product. This observation proved that the catalytic process was heterogeneous.

A novel approach for the construction of palladium nanoparticles (PdNPs) supported on a carbon-based graphene oxide (GO) monolith has been described by Nakhate and his co-workers [72]. It was fabricated by the carbonization of glucose with a small amount of graphene oxide as a structure directing agent, which offers a large surface area for the dispersion of palladium nanoparticles. The carbon-based graphene oxide monolith reduced the leaching of PdNPs into the reaction mixture and increased the rate of interaction between the support and the nanoparticles.



The developed catalyst was found to be effective for Sonogashira cross-coupling reaction and hydrogenation of alkene and nitrobenzene. The catalytic efficiency of the Pd@CGO monolith was compared with 5% Pd/C and 5% Pd@GO for the Sonogashira coupling of iodobenzene with phenyl-acetylene. The Pd@CGO monolith exhibited superb reactivity towards the Sonogashira cross-coupling reaction of iodobenzene with phenylacetylene leading to 93% conversion of the coupling products without the use of copper and ligand at 90 ^{0}C (Scheme **12**). Iodobenzene, substituted with electron-withdrawing groups easily transformed to the corresponding diphenylethyne as coupling products in good to excellent yields. Good to excellent yields of desired products were also obtained with iodobenzene, substituted with electron-donating groups. It is interesting to note that less reactive bromobenzenes smoothly reacted with phenylacetylene to furnish desired products in good yields. The author also proposed the reaction mechanism and kinetic equation. The hot filtration test showed that the catalyst has high stability and could be reused at least four times without loss of activity.

Scheme (12). Sonogashira cross-coupling catalyzed by Pd@CGO catalyst.

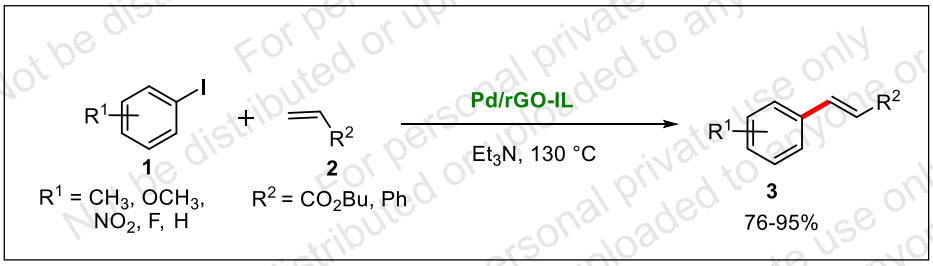


REDUCED GRAPHENE OXIDE (RGO) SUPPORTED PALLADIUM NANOPARTICLES (PDNPS-RGO) CATALYZED COUPLING REACTIONS

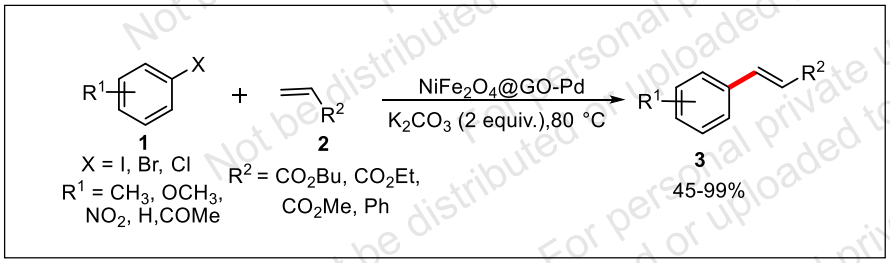
In 2014, Shendage and co-workers developed electrochemically co-deposited palladium nanoparticles (PdNPs) supported on a reduced graphene oxide (ERGO-Pd) catalyst and used for Suzuki cross-coupling reactions [73]. They observed that PdNPs with smaller sizes in ranges from 3 to 9 nm exhibited high catalytic activity. The prepared catalyst has major advantages such as a high degree of catalytic activity, chemical stability, selectivity, and reusability up to six times. This catalytic system generates a library of biphenyl derivatives using K_2CO_3 as a base in ethanol under reflux conditions, whereas lower yield was observed at room temperature (Scheme **13**). Several aryl halides having electron-withdrawing as well as electron-donating groups smoothly coupled with various phenylboronic acids to form coupling products in good to excellent. Aryl iodide provides better results in compassion to aryl bromides in terms of yield and time. There are many analytical techniques such as SEM (scanning electron microscopy), TEM (transmission electron microscopy), X-Ray analysis, and EDAX (energy dispersive X-ray analysis) have been used to characterize the catalyst.

Scheme (13). Suzuki coupling reaction catalyzed by ERGO-Pd.

Later, the same research group reported co-deposited palladium nanoparticles (Pd NPs) supported on reduced graphene oxide (ERGO-Pd) catalyzed carbon-carbon cross-coupling Heck reactions [74]. Under this catalytic system, several aryl halide bearing either electron-withdrawing or electron-donating groups reacted with different styrene and acrylate to generate a series of substituted stilbenes and cinnamates in good to excellent yields (Scheme **14**). Aryl bromides take a longer time due to high bond dissociation energy in comparison to aryl iodide. The reusability of this catalyst is high and can be recycled up to four to five times without loss of activity.



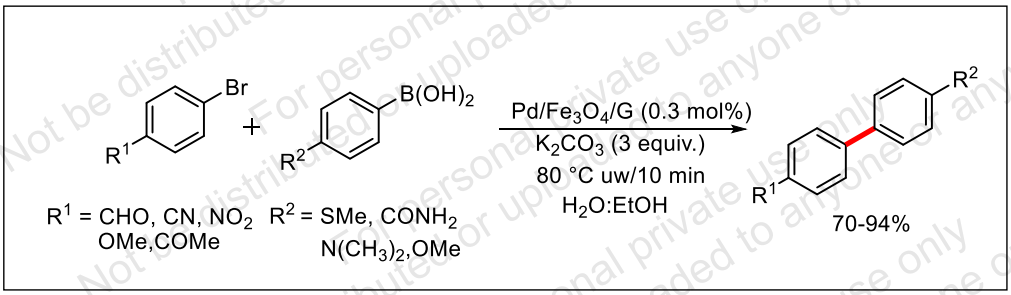
Scheme (14). Heck cross-coupling reaction catalyzed by ERGO-Pd.



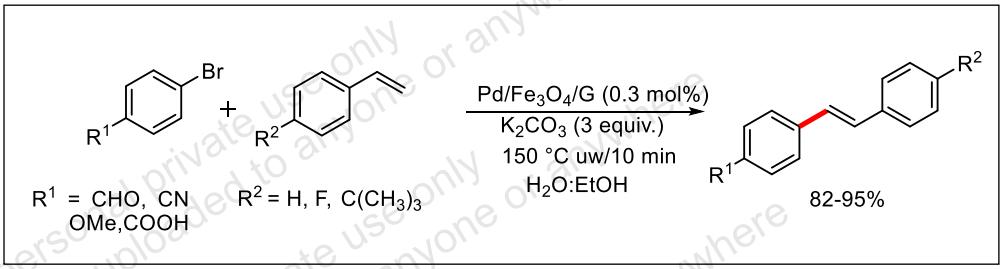
In 2015, a new multi-step protocol for in-situ generation of palladium nanoparticles supported on reduced graphene oxide using 1-butyl-3-methylimidazolium hexafluorophosphate ([BMIM]PF_6) ionic liquid by phase-transfer method (Pd/rGO-IL) in aqueous medium was developed by Liu and co-workers [75]. In-situ generated catalyst having an average particle size of 2 nm and uniformly dispersed on the surface of reduced graphene oxide was confirmed by TEM images. The synthesized catalyst showed excellent activity for Heck cross-coupling reactions of iodobenzene with butyl acrylate. The reactions were performed using a catalytic amount of Pd/RGO-IL in the presence of Et_3N as a base at 130 ^{0}C; in which iodobenzene-bearing electron-withdrawing or electron-donating groups coupled with acrylate to provide a moderate yield of desired products with 76-87% conversion. However, neutral iodobenzene reacted with acrylate and styrene to give coupling products in excellent yields with 95% and 92% conversion respectively (Scheme **15**). The reusability of the catalyst was also studied and found that it can be recycled up to ten times without significant loss of catalytic activity, which showed that it has high catalytic stability. The high stability of the catalyst might be due to the double protection of the organic cation [BMIM]+ of IL and reduced graphene oxide (rGO) which could be helpful in the reduction of collision and agglomeration of Pd nanoparticles.

In 2015, the research group of Liu developed an effective and eco-friendly protocol for the synthesis of multimetallic nanoparticles catalyst, especially

magnetically separable Pd NPs supported on graphene oxide [76]. The polymetallic graphene oxide supported PdNPs ($NiFe_2O_4$@GO-Pd) hybrids were obtained from $PdCl_2$, $FeCl_3.6H_2O$, and $NiCl_2.4H_2O$ in ethanol-ethylene glycol using hydrothermal treatment. The $NiFe_2O_4$ were uniformly dispersed on the surface of graphene oxide without help of any linker molecules, which help in providing ion transport channels to bridge the NPs and the matrix. The authors have also demonstrated the catalytic power of this synthesized catalyst for Heck cross-coupling reactions of aryl halides with substituted olefins. Iodobenzene-bearing electron-donating or electron-withdrawing groups efficiently reacted with olefins in the presence of (0.08 mol% Pd) $NiFe_2O_4$@GO-Pd catalyst and 2.0 equiv. of K_2CO_3 as a base in EtOH-H_2O at 80°C to provide coupling products in excellent yield (Scheme **16**). A slightly decreased yield of the coupling product was obtained with iodobenzene having a methyl group at the ortho position. Bromobenzene reacted with styrene to furnish a moderate yield of coupling product under the same catalytic system. However, chlorobenzene provides a lower yield of the desired product even after increasing the catalyst loading and reaction time. The most attractive feature of this catalyst was its recyclability and stability, it can be recycled up to six times without the loss of catalytic activity supported by ICP-MS analysis. The $NiFe_2O_4$@GO-Pd catalyst showed high catalytic power and stability towards the Heck cross-coupling reactions in comparison to $NiFe_2O_4$-Pd catalyst because of the supportive role of graphene oxide for $NiFe_2O_4$@GO-Pd, which reduces the agglomeration of Pd nanoparticles.



Scheme (15). Heck reaction catalyzed by Pd/RGO-IL.

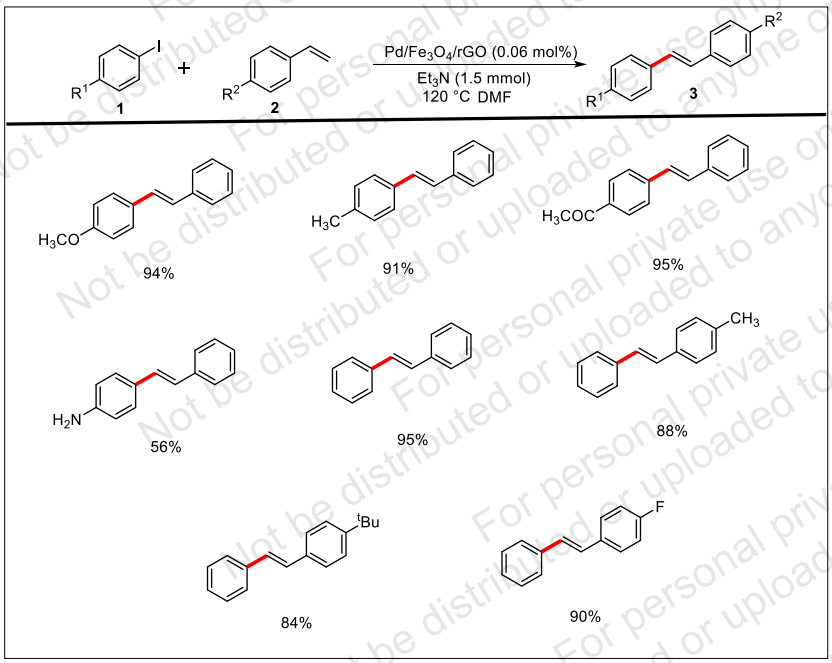


Scheme (16). $NiFe_2O_4$@GO-Pd catalyzed Heck cross-coupling reaction.

Another important approach for the construction of highly active Pd/Fe_3O_4 nanoparticles supported on graphene ($Pd/Fe_3O_4/G$) has been described by Elazab and co-workers in 2015 [77]. The catalyst ($Pd/Fe_3O_4/G$) was synthesized by microwave-assisted reduction of palladium nitrate, ferric nitrate, and graphene oxide using hydrazine hydrate as the reducing agent in an aqueous medium. The constructed magnetic catalyst ($Pd/Fe_3O_4/G$) showed exceptional catalytic activity for cross-coupling reactions (Heck and Suzuki cross-coupling reaction). The most striking feature of this magnetic catalyst is that it shows a high turnover number (TON) of 9250 and a turnover frequency (TOF) of 111,000 h^{-1} for Suzuki and Heck cross-coupling reactions. The catalytic performance was first studied for Suzuki cross-coupling reactions and found that a wide range of functionalized aryl halides efficiently coupled with aryl boronic acid in the presence of 0.3 mol% of catalyst using K_2CO_3 as a base in H_2O:EtOH as a solvent to provide the corresponding biphenyl products in moderate to excellent yield (Scheme **17**). Arylhalide-bearing electron-withdrawing groups such as aldehyde, ketone, nitro, and nitrile furnished the corresponding biphenyl derivatives in excellent yield, whereas chlorobenzene provided the Suzuki cross-coupling product in a relatively good yield. However, boronic acid containing electron-donating groups (dimethyl amino, thiomethyl, and *p*-methoxy) smoothly converted into biphenyl derivatives with aryl halides in excellent yield.

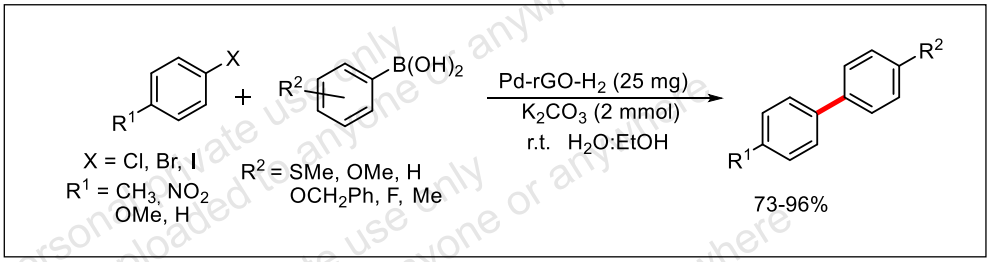
Scheme (17). Suzuki reaction catalyzed by $Pd/Fe_3O_4/G$.

The catalytic efficiency of this catalyst was further checked for Heck cross-coupling reactions. The catalyst was found to be highly active towards the Heck reactions of different aryl iodides/bromides with substituted styrenes/acrylates using 0.3 mol% of catalyst and K_2CO_3 (3 eq.) as a base in H_2O:EtOH at 150 ^0C under microwave irradiation. The reaction provided the corresponding products in excellent yields in cases of bromobenzene-bearing electron-donating and electron-withdrawing groups. These results prove the outstanding activity of this catalyst. The catalyst can be recovered and further used up to ten times without significant loss of catalytic activity (Scheme **18**).



Scheme (18). Heck cross-coupling reaction catalyzed by $Pd/Fe_3O_4/G$.

Recently, a similar approach for the preparation of magnetically recoverable palladium nanoparticles supported on graphene oxide has been developed by Fu's research workers [78]. In the development of $Pd\text{-}Fe_3O_4/rGO$, $FeCl_2.4H_2O$ was used as a starting material reacting with ammonium hydroxide to form iron hydroxide followed by simultaneously oxidation and dehydration to form Fe_3O_4 nanoparticles at high temperature and pressure whereas Pd nanoparticles were dispersed onto the surface of graphene oxide using ethanol as the reducing agent under the ultrasonic and hydrothermal strategy. Concurrently, the Fe_3O_4 NPs were well dispersed on two-dimensional rGO nanosheets and formed $Pd\text{-}Fe_3O_4/rGO$ nanohybrids materials through a self-assembly approach. The synthesized catalyst was characterized using various analytical techniques. TEM images displayed that both palladium nanoparticles and iron oxide nanoparticles were homogeneously distributed onto the surface of reduced graphene oxide nanosheets, whereas HRTEM images indicate the size of nanoparticles up to 2 nm and no agglomeration on the surface of graphene oxide.



The formed catalyst was used to evaluate its catalytic efficiency for Heck cross-coupling of 4-iodoanisole and styrene. A wide range of iodobenzene reacted with styrenes in the presence of 0.06 mol% catalyst using triethylamine as a base in DMF as solvent at 120 ^{0}C to provide the corresponding coupling products in moderate to excellent yields. Iodobenzene-bearing electron-withdrawing groups efficiently coupled with styrene to give the cross-coupling products in excellent yields, whereas iodobenzene with an amino group at the para position provides the corresponding product in lower yield (Scheme **19**). The reusability of this catalyst was also examined and found that the recovered catalyst can be consecutively recycled up to six times without significant loss of catalytic power. These results indicate that this catalyst has high catalytic efficiency and is beneficial to both the environmental and economic perspectives.

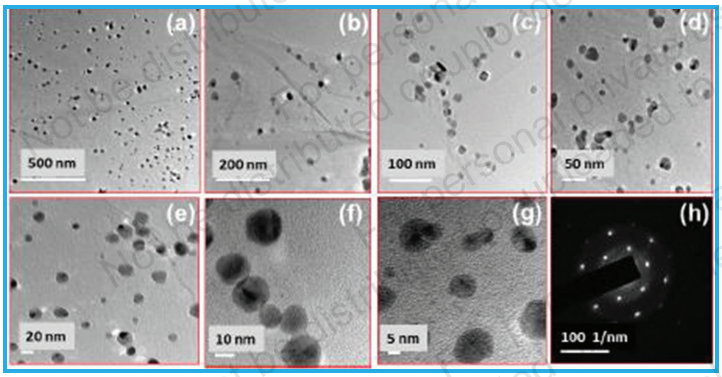
Another important approach for the synthesis of palladium nanoparticles supported on graphene oxide using hydrogen gas as the reducing agent has been

developed by Hussain and his co-workers [79]. The catalyst was synthesized by the following methods, involving reduction of graphene oxide followed by dispersion of palladium nanoparticles on the surface of reduced graphene oxide nanosheets and simultaneously reduction of olefin. The synthesized catalyst was found to be more effective towards the cross-coupling reactions of aryl iodides with phenylboronic acids (Scheme **20**). Iodobenzene that incorporated electron-donating and electron-withdrawing substituents smoothly coupled with arylboronic acids under the catalytic system (Pd-rGO-H_2 (25 mg), Na_2CO_3 (2 mmol), H_2O:EtOH (10 mL, 1:1), r.t) providing the corresponding biphenyl analogous in moderate to excellent yields. It is interesting to note that phenylboronic acid neopentylglycol ester was used in place of boronic acid as a coupling partner for the Suzuki cross-coupling with bromobenzene to give the coupling product in an excellent yield under the same catalytic system. However, the use of chlorobenzene as a coupling partner with arylboronic acid gave a slightly lower yield of the coupling product even after increasing the reaction time and reaction temperature. The most important feature of this catalyst was its reusability. The recovered catalyst can be recycled up to four times without loss of catalytic activity for Suzuki cross-coupling reactions. However, the catalytic performance decreased up to 62% after the fourth run might be due to the decrease in the surface area.

Scheme (19). Synthesis of biphenyl styrenes by Heck cross-coupling reaction using Pd-Fe_3O_4/rGO.

Scheme (20). Suzuki cross-coupling reaction catalyzed by Pd-rGO-H_2.

In 2018, the Raiza research group reported a biogenic one-pot strategy for the synthesis of graphene-supported palladium nanoparticle (Pd Nps/rGO) catalyst using reduced graphene oxide (rGO) and H_2PdCl_4 as starting material followed by reduction with *Ficus carica* fruit juice as the reducing agent and Poly(*N*-vinyl-2-pyrrolidone) (PVP) as stabilizing agent [80]. The Ultraviolet-Visible spectroscopy (UV-Vis) displaced the complete reduction of ions and the formation of PdNP and PdNP/rGO. TEM images showed the homogeneous distribution of PdNPs on the surface of rGO with a smaller particle size in a spherical shape. The HRTEM image confirmed the crystal lattice of PdNPs and the edges of rGO nanosheets to be ~16 nm. The crystalline nature of observed using the SAED image (Fig. **1**). The formed catalyst was examined in Suzuki cross-coupling reactions using aryl halides with phenylboronic acids. A variety of biphenyl derivatives have been synthesized in good to excellent yields using 0.96 mol%, K_2CO_3 as a base and water: ethanol as solvent at 180 ^{0}C. The reduced yield was observed after decreasing the catalyst loading from 0.96 mol% to 0.5 mol% whereas no yield of coupling products were observed after increasing catalyst loading. The reusability of the catalyst in Suzuki cross-coupling was examined and found that the catalyst can be used ten times without loss of activity.



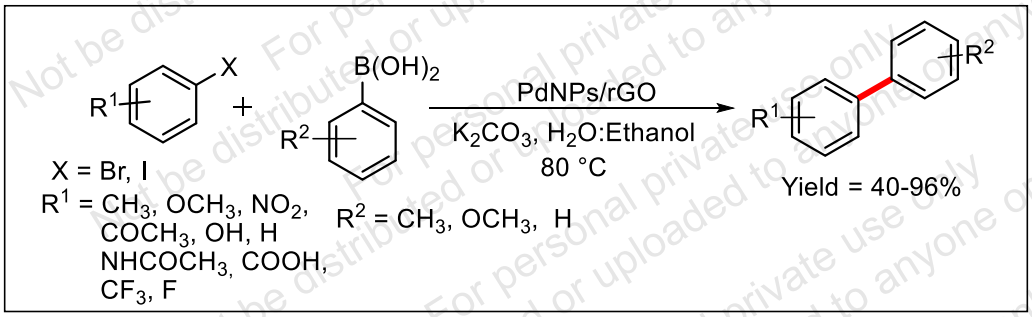


Fig. (1). Transmission electron microscopy images. (**a-e**) Images along with particle size distribution; (**g**) HETEM image along with fringe spacing; and (**f**) SAED image of the PdNP/rGO.

In 2018, Kulkarni and co-workers developed an eco-friendly protocol for the synthesis of graphene oxide supported palladium nanoparticle catalyst using graphene oxide, $PdCl_2$ as the precursor, followed by reduction with aloe vera extract as the reducing agent in the presence of sunlight as an energy source [81]. The prepared catalyst was characterized using different analytical techniques.

SEM image confirmed the formation of PdNPs on reduced graphene oxide with a uniform dispersion of PdNPs whereas the TEM image indicated the presence of PdNPs on the surface of rGO with an average particle size of 2-19 nm. The catalytic performance of the synthesized catalyst was examined in Suzuki cross-coupling reactions. The authors obtained several coupling products in good to excellent yields, when the reaction was performed using aryl halides with phenylboronic acid in the presence of 0.2 mol% of catalyst K_2CO_3 as a base and water: ethanol as solvent at 80 ^{0}C (Scheme **21**). Aryl iodide having electron-donating or electron-withdrawing groups was more reactive towards the phenylboronic acid providing exceptional results in terms of yield and reaction time, whereas aryl bromide/aryl chloride was less reactive with phenyl boronic acid under same the reaction conditions. The recovery of the catalyst was also studied and found that it could be reused seven times without significant loss of activity. A considerable loss of activity of the catalyst was seen after the 7th cycle due to agglomeration and an increase in particle size of palladium nanoparticles on reduced graphene oxide.

Scheme (21). Suzuki cross-coupling reaction catalyzed by PdNPs/rGO.

In 2016, Mahanta and co-workers described an eco-friendly copper-free Sonogashira cross-coupling reaction catalyzed by palladium nanoparticles supported on reduced graphene oxide at room temperature in ethanol [82]. PdNPs were synthesized using hydrogen gas as a reducing agent to generate PdNPs supported on reduced graphene oxide sheets. The catalytic performance of the catalyst was investigated for the Sonogashira cross-coupling reaction. The reactions proceeded smoothly using 5 wt% of the catalyst in the presence of

K_2CO_3 as a base at room temperature in ethanol to provide the coupling products with good to excellent yield (see Table 2). The alkyne bearing electron-donating or electron-withdrawing groups was coupled with aryl halides to furnish the biphenylacetylene derivatives in excellent to good yield. However, non-aromatic alkynes such as cyclohexylacetylene were coupled with different iodides to provide the coupling products in moderate yield under the same catalytic system. Moreover, bromobenzene did not provide a satisfactory yield of the coupling products even after increasing the reaction time (Table **2**, entries 11 and 12). The reusability of the catalyst was also studied and observed that it could be recycled up to six times without loss of minimal activity.

Recently, the research group of Tarahomi has employed the Pd catalyst supported on dendrimer-functionalized graphene oxide for Sonogashira cross-coupling reaction [83]. The dendrimer-based palladium catalyst was developed in multistep. The first step involves the reaction of GO with $FeCl_2.4H_2O$, and $FeCl_3.4H_2O$ followed by the addition of 1 mL of NH_3-H_2O to get magnetic graphene oxide (MGO), then MGO was covalently attached with modified PAMAM dendrimer (G. 2) in the presence of EDC/NHS [84].

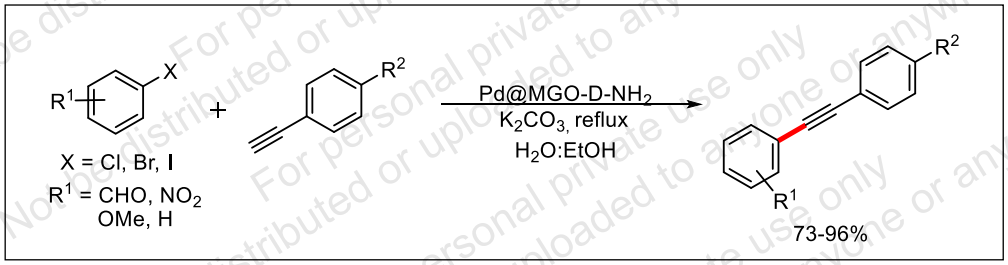

Table 2. Scope of Sonogashira coupling reaction catalyzed by PdNPs@GO.

Entry	R^1	R^2	X	Time	Yield
1	4-NO_2	C_6H_5	I	7	94
2	3-Me	C_6H_5	I	7	96
3	4-Me	C_6H_5	I	8	95
4	3-NO_2	C_6H_5	I	8	95
5	4-OMe	C_6H_5	I	8	92
6	H	C_6H_5	I	7	96
7	4-Me	4-MeC_6H_5	I	7	98
8	4-Me	C_6H_{11}	I	10	85
9	H	C_6H_{11}	I	10	80
10	4-OMe	4-MeC_6H_5	I	7.5	98
11	4-NO_2	C_6H_5	Br	12	47
12	4-OMe	C_6H_5	Br	12	53

[a]Reaction conditions: acetylene (0.75 mmol), aryl halide (0.5 mmol) [b]Isolated yield: purified by column chromatography.

Subsequently, PdNPs were dispersed on the surface of dendrimer-functionalized graphene oxide through graft interactions between free chelating amino groups of dendrimer and Pd precursor. The most attractive feature of these nanocomposite

materials was not only solubility in an aqueous medium but also stabilized metal NPs on their surfaces. The structural characterization of this catalyst was confirmed by using different analytical techniques such as TEM, BET, FTIR, and elemental mapping analysis. The catalytic power of this catalyst was checked for the Sonogashira cross-coupling reaction. The Sonogashira cross-coupling reaction works very well for alkynes and aryl halides in the presence of dendrimer-supported palladium catalyst to furnish corresponding products in excellent yields, except for chlorobenzene which gave a lower yield of the desired product (Scheme **22**). Regarding the mechanism, it was proposed that the reaction is initiated by the coordination of the Pd@MGO-D-NH_2 catalyst to the C-C triple bond of phenylacetylene followed by the deprotonation of terminal C-H of alkyne with K_2CO_3 to form potassium acetylide. Pd@MGO-D-NH_2 catalyst also activates the aryl halide (ArX) and forms aryl palladium halide complex (ArPdX) and then halide displacement takes place to form an aryl palladium acetylide. Subsequently, reductive elimination takes place to give a cross-coupling product with a regeneration catalyst. The reusability of this catalyst was also studied and found that it could be reused up to four times without significant loss of catalytic power.

Scheme (22). Pd@MGO-D-NH_2 catalyzed Sonogashira coupling reaction.

CONCLUDING REMARKS

In this chapter, we focused on metal-supported graphene oxide for its catalytic potential. The prepared heterogeneous catalysts were beneficially used for C-C bond formation using different cross-coupling reactions such as Mizoroki-Heck, Suzuki-Miyaura, Kumada, Stille, Negishi, Hiyama, and Buchwald-Hartwig, *etc.* In a prevalent number of examples, the comparison of heterogeneous catalysts with corresponding homogeneous catalysts has been observed. The advantages of the discussed heterogeneous catalysts consisted of their simple preparation, inexpensive and easily available starting materials, their simple isolation, and the possibility of reuse. Easy performance of the reaction in aqueous media brings great benefits in the case of several cross-coupling reactions. Several of the described reactions possibly have a high potential for industrial usage, hence the

catalytic systems presented in this chapter significantly contribute to the further development of green chemical processes.

LIST OF ABBREVIATIONS

AAPTMS	[3-(2-Aminoethylamino)propyl] trimethoxysilane
BET	Brunauer–Emmett–Teller
$ClPPh_2$	Chlorodiphenylphosphine
2D	Two dimensional
EPD	Electrophoretic deposition
ERGO-Pd	Electrochemically codeposited palladium nanoparticles supported on reduced graphene oxide
EDAX	Energy dispersive X-ray analysis
EDC2	ethyl(dimethylaminopropyl) carbodiimide
FESEM	Field emission scanning electron microscopy
FTIR	Fourier Transform Infrared Spectroscopy
GO	Graphene oxide
G-BI-Pd	Graphene-benzimidazole
GOH	Hydroxyl group on the surface of graphene
GNS	Graphite nanosheet
HRTEM	High-resolution transmission electron microscopy
ICP-AES	Nductively coupled plasma atomic emission spectroscopy
LAL	Laser ablation in liquids
NHS	N-Hydroxysuccinimide
PdNPs	Palladium nanoparticles
PdNPs-G	Palladium nanoparticles supported on graphene
PdNPs-rGO	Palladium nanoparticles reduced graphene oxide
Pd/graphene	Graphene supported Pd
PFG	Phosphine functionalized graphene
PFG	Phosphine grafted graphene oxide
Pd-slGO	Palladium nanoparticles supported on single layer oxide
Pd@GOF	Palladium nanoparticles catalyst supported on graphene oxide framework
PCA-GNS-Pd	Pyrenecarboxylic acid graphite nanosheet supported Palladium
PVP	Poly(N-vinyl-2-pyrrolidone)
PAMAM	Polyamidoamine
r-GO	Reduced graphene oxide
SEA	Strong electrostatic adsorption

Abstract: The research on the development of high-performance metal-free carbocatalysis is one of the emerging areas in chemical sciences. The possible active sites of the surfaces of graphene, oxygenated, and reduced graphene oxide materials are responsible for diversified synthetic transformations, including redox reactions. At present, the advanced research is focused on scalable, sustainable, biocompatible, green, and cost-effective graphene-based carbocatalysts as wonderful alternatives over the noble metallic catalytic materials which are being employed despite their scarcity, high cost, and relative toxicity. The present chapter describes the utility of graphene-based carbocatalysts in multicomponent reactions.

Keywords: Catalytic Activity, Graphene Oxide Materials, Metal-Free Carbocatalysts, Multicomponent Reactions, Reduced Graphene Oxides.

1. INTRODUCTION

Numerous organic transformations have been reported by many homogeneous transition metal complexes including organometallics and heterogeneous catalysts [1 - 4]. Among these catalytic reactions, due to the significant medicinal properties of the reaction products, various multicomponent organic reactions yielding fused heterocyclic compounds have been designed employing a variety

* **Corresponding author Akella Sivaramakrishna:** Department of Chemistry, School of Advanced Sciences, Vellore Institute of Technology (VIT), Vellore 632014, Tamil Nadu, India; E-mail: asrkrishna@vit.ac.in
ψ All these authors have equal contributions to this Chapter.

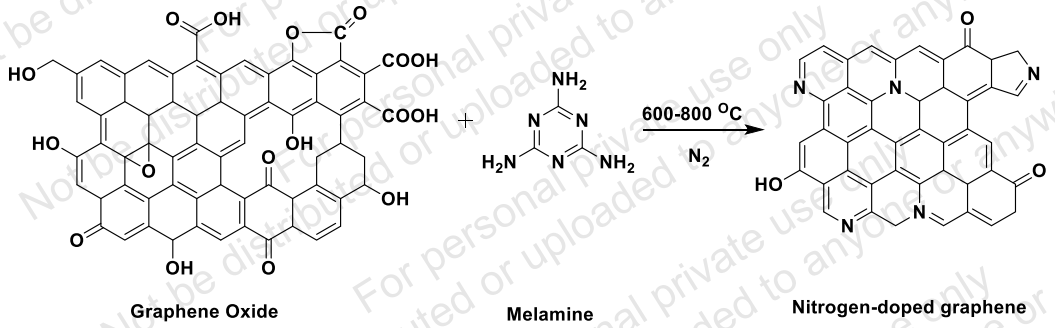
of metal and non-metal-based catalysts [5]. It would be appropriate to design alternative non-metal catalysts derived from renewable resources in terms of sustainability. Because of this, carbon materials resulting from biomass have been considered sustainable pathways [6, 7]. The economic burden and toxicity are the other specific factors besides sustainability, which favor the carbocatalysts since some of the precious metals (in particular noble metals) are very expensive over the carbon feedstock materials. Furthermore, it is sometimes a very difficult task to remove the residual catalyst from the final product, which can lead to undesired toxicity. These aspects are the driving force in developing metal-free catalysts by researchers. Among them, "carbocatalysis" is one of the promising sustainable routes to reduce metal-based reactions [8 - 10]. It was found that these carbocatalysts, especially the heteroatom doped graphene-based carbocatalysts are considered the best promising alternates of noble metals as an efficient and green catalyst.



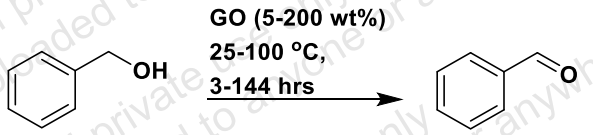
In general, carbocatalysts are non-molecular entities and contain mostly carbon framework as an active component with a large surface area. But these carbonaceous catalytic materials are completely different from organocatalysts, which are active organic molecules [7, 11]. Furthermore, the incorporation of the active sites into the carbon materials by appropriate modifications is the key aspect for carbocatalysts, which makes the utilization of metals non-essential. Carbocatalyst is better suited for heterogeneous reactions over homogeneous systems when the particle sizes are large. However, the particle size of the graphene material can be reduced to the carbon dots having 2D morphology; carbocatalysts facilitate the single phased homogeneous catalysis [12]. The graphene derivatives can offer wonderful catalytic properties due to the presence of functional groups with heteroatoms on the G-sheet as active catalytic centers [13, 14]. The importance of graphene as catalytic material is highlighted based on the adsorption capacity, electron density, and morphology of the sheets and its efficiency is strongly dependent on the position and nature of active sites on the graphene sheets.

2. SYNTHESIS OF GRAPHENE-BASED CARBOCATALYSTS

A large number of research articles have been reported on the method of preparation on various Gmat [12 - 33] and characterization techniques [17, 18, 23, 34], including their important structural properties for the applications in electronics [34 - 40] and conductivity [38 - 41]. Furthermore, the studies on electrocatalysis [42 - 47] and photocatalytic applications [48] of graphene derivatives have been widely carried out; however, there is a growing interest in the graphene oxide (GO) materials as semiconductors [49] and the synthesis of

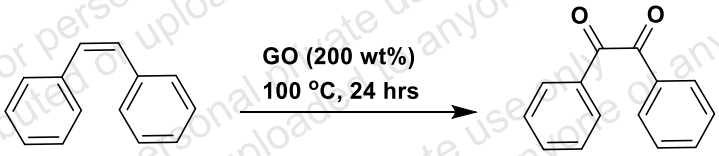
organic heterocycles [50]. Notably, N and P double doped graphene carbon catalyst (NP-G) was employed for the reduction of nitrophenol over traditional graphene-based catalyst [14]. Nitrogen and sulfur co-doped graphene (NS-G) derived by one-pot thermal pyrolysis using heteroatom containing precursors like dopamine hydrochloride (DA) and 2-mercaptoethanol (ME) exhibits unusual catalytic activity due to its porous structure toward water splitting upon activation [51].

The synthesis of heteroatom donor graphene oxide (GO) is quite lengthy and cumbersome. Primarily, the modified Hummer's method [52] was employed to synthesize GO for the synthesis of N-doped rGO. By this process, GO was (1.0 g) dissolved in 50 mL ethanol, agitated for around 30 min, followed by sonication. After that, melamine (1.0 g) was incorporated into the mixture and the resulting suspension was heated to 50 °C on a hotplate while stirring (Scheme **1**). The desiccated mixture was heated at 450 °C and then calcination was done at varying temperatures of 600, 700, and 800 °C under an inert N_2 atmosphere for 1 h to obtain NG-600, NG-700, NG-800, respectively. Further washing with ultrapure water and ethanol and after overnight drying at 60 °C, the (N)G attains the catalytic activity [53].



Scheme 1. Synthesis of N-doped graphene.

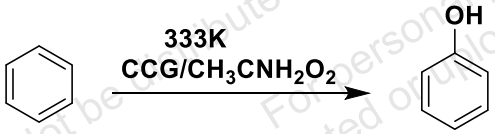
The graphene-based carbocatalytic reactions for various organic transformations are broadly classified into i) oxidation, ii) carbon-carbon bond formation, iii) hydrogenation, iv) aza-Michael addition, v) dehydration-hydrothiolation, and vi) Friedel-Crafts alkylation.



3. ORGANIC TRANSFORMATIONS BY GRAPHENE-BASED CARBOCATALYSIS

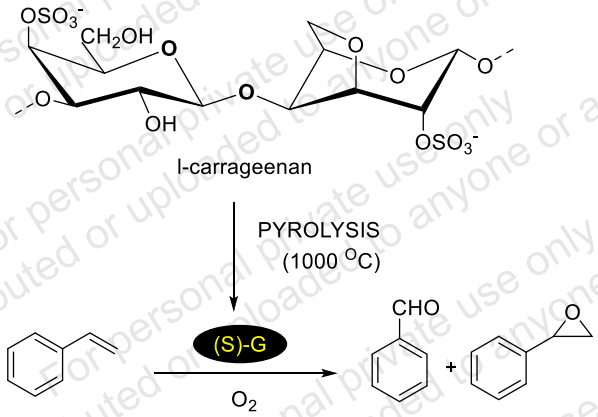
3.1. Oxidation Reactions

Similar to transition metal-based catalysts facilitating efficient incorporation of an oxygen atom into organic molecules by oxidation reactions, graphene oxide-based catalysts are also mild but effective carbocatalysts for oxidation reactions as given in Scheme **2** and Scheme **3** [54].



Scheme 2. Oxidation reaction of benzyl alcohol to benzaldehyde (92%) with GO catalyst.

Scheme 3. Oxidation of *cis*-stilbene in to dione (49%) with GO catalyst.



The conversion of benzene to oxygen-containing aromatic compounds is one of the most active and still evolving fields of catalysis due to its industrial significance. But they are typically prepared by long processes that are both expensive and time-consuming (*e.g.* phenol produced by 3-step cumene processes as given in Scheme **4**). There are also other disadvantages, such as contamination and less selectivity towards compounds. A lot of changes and improvisations have been made to enhance this field of catalysis. Nano-sized carbon materials, such as graphene, have proven to be effective and selective catalysts for such reactions. The reason for the improved catalytic activity is due to the open π-electron system and the huge adsorption rate of graphene [55].

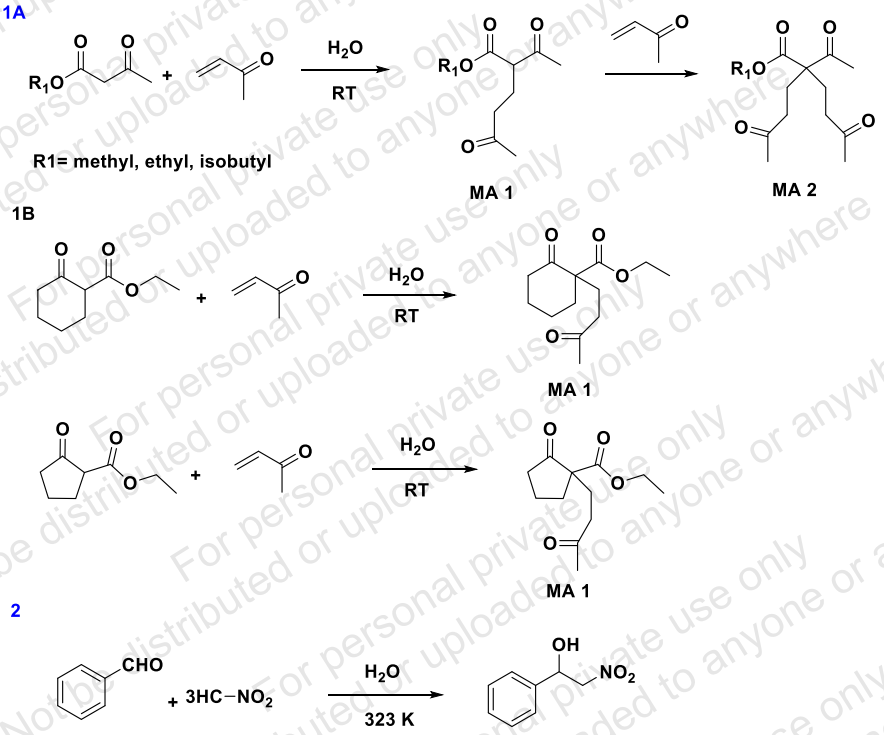
Scheme 4. Oxidation of benzene to phenol (> 99%) using CCG as a catalyst.

Traditionally the styrene was oxidized to benzaldehyde and benzoic acid by molecular oxygen, but it was investigated that the styrene oxide was also getting formed through epoxidation. So far it was extremely difficult to monitor the

reaction so that it should not form unpleasant side products and undergo detrimental reactions. The interest of this (S)G synthesis arrived in minds of researchers from the fact that the oxidation of the alkene in aerobic conditions using transition or noble metals as the catalysts, and, hence it would be exceptionally profitable to formulate such catalysts which must be metal-free for such processes. The monitored reaction was done in the absence of catalyst which has led to only 4% product formation. This is attributed due to auto-oxidation. Moreover, the reaction was assessed by oxidation of styrene under aerobic and non-solvent reaction conditions in presence of (S)G as a catalyst. Promisingly, 13% of conversion was achieved after 7 h with 70 and 20% of benzaldehyde and styrene oxide respectively (Scheme **5**). The hallmark of (S)G catalyst is that it could be reused or recycled two times with no considerable changes in selectivity and efficiency [56].

Scheme 5. Oxidation of styrene in the presence of graphene S-doped to benzaldehyde (100% selectivity at 100 ºC) and to styrene oxide (maxmum 20% selectivity).

Further, the use of a metal-free sulfonic acid-functionalized reduced graphene oxide (SA-rGO) material for catalytic synthesis of carboxylic acids and its corresponding bio-isosteres, 5-substituted-1H-tetrazoles, has been reported. As a catalytic material, SA-rGO combines the intriguing properties of graphene oxide with the added benefit of highly acidic sites due to sulfonic acid groups. H_2O_2 as a green oxidant with high TOF values (9.06–9.89 h^{-1}) was used to oxidize aldehydes to carboxylic acids very efficiently. Similarly, the 5-substituted-1H-tetrazoles could also be synthesized efficiently with high TOF values (12.08–16.96 h^{-1}). By employing the SA-rGO catalyst, both reactions could be carried out efficiently at the gram scale level (10 g). SA-rGO has high reusability of up to eight runs without a significant decrease in productivity. As a result of these features, SA-rGO is an attractive alternative from the industrial point of view [57].



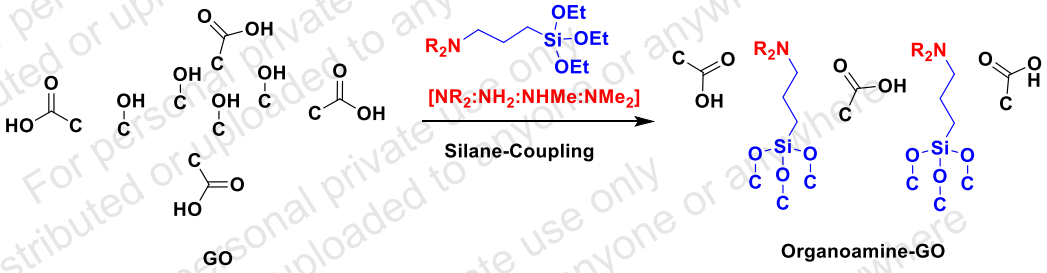
Notably, the graphene oxide reduction method influences the activity of the resulting reduced graphene oxide (rGO) for the aerobic oxidation of benzylamine. Beginning with GO obtained *via* the Hummers method, a series of rGO samples was prepared *via* chemical (hydroquinone (HQ), hydrazine (HZ), or ascorbic acid (ASC)) or thermal reduction. The analysis reveals that the chemical reducing agents reduce GO with different functional groups affecting the catalytic activity of the resulting rGO for molecular oxygen activation in the oxidation of benzylamine. The rGO-HQ1 sample prepared with HQ as a reducing agent exhibited the optimum activity in the aerobic oxidation of benzylamine at 80 °C. It has been hypothesized that HQ introduces hydroquinone/*p*-benzoquinone-like moieties onto the graphene sheet and these active sites are responsible for the oxidation reaction. By selective masking of oxygen functional groups present in the most active rGO sample, indicates the activity of HQ and/or *p*-benzoquinone as organocatalysts. In five consecutive uses, the most active rGO sample displayed good reusability and stability. Hydroperoxyl radicals were presumed as the primary reactive oxygen species formed in the system, according to selective quenching tests [58].

Anumula *et. al*. reported glutathione-protected Ag_6 clusters using a simple green reaction, transferred them to graphene oxide (GO), and used them as a catalyst for cyclohexane oxidation under ambient conditions. With *t*-butyl hydroperoxide (TBHP) as the oxidant in an oxygen-flowing atmosphere, high selectivity and yield of cyclohexanone is obtained. It is demonstrated that using density functional theory calculations that both TBHP and oxygen interact with the Ag6 clusters supported by GO, resulting in the peroxide structure and thus facilitating catalysis cyclohexane oxidation. It is interesting to note that hydrogen-added hydroperoxyl (-OOH) has a significantly lower activation barrier for O-O bond dissociation. The O-O dissociated intermediate then reacts with cyclohexane to form cyclohexanol, which is then dehydrogenated by successive oxidative reactions to form cyclohexanone. This finding validates the enhanced catalysis of TBHP and O_2 for the conversion of cyclohexane to cyclohexanone and contributes to the development of heterogeneous metal cluster catalysts for efficient C-H activation [59].

Reports show that by reacting respective ultra-small colloidal metal oxide/hydroxide with partially reduced colloidal graphene oxide, surfactant-free MGN for distinct noble metals can be prepared for high-performance fuel cell catalysis. The resulting MGN is made up of widely distributed M-M^{+n} based nanoparticles with extremely small sizes that provide a strong and stable catalytic current for the oxidation of ethanol and formic acid [60].

3.2. Carbon-Carbon Bond Formation

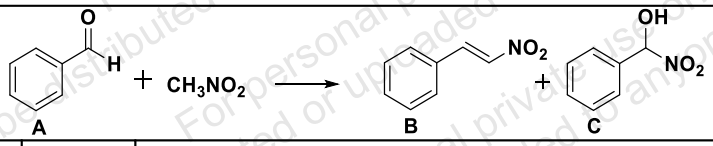
Besides, *N*-doped defective graphene [(N)G] carbocatalyst was synthesized by pyrolysis of chitosan and employed as a basic catalyst for some C-C bond forming reactions which are nucleophilic Michael and Henry additions as shown in Scheme **6**. The most basic *N*-sites were detected by DFT calculations amongst pyridinic, pyrrolic, and graphitic residual nitrogen atoms of *N*-doped defective graphene [61].



Scheme 6. Some C-C bond forming reactions through nucleophilic Michael and Henry additions by carbocatalysis.

Also, the fabrication of sulfur-doped graphene oxide (SA-GO) by the method of sulfuration and alkylation was reported [62].

Remarkably, GO-supported primary amine (AP-GO) facilitated one-pot Henry-Michael reactions provide synthetically profitable multi-functionalized nitroalkanes. Furthermore, the higher activity is recorded with GO-supported system more than those activated carbon-supported primary amine, and mesoporous silica-supported primary amine as catalysts. This predominant catalytic performance started from the interesting properties of AP-GO, which is based on the acid−base cooperative effect by the suitable primary amines on their



basal planes and the carboxyl acids along their edges. The decreased diffusion resistance of the reactants and intermediates are responsible for the multistep catalytic cycles. Also, it may be promptly reused by simple filtration and consequently recycled without significant loss of its catalytic activity. The organoamines were anchored on the basal planes of GO through a basic and simple silane-coupling reaction to manage GO-supported organic amines, as depicted in Scheme **7** [63].

Scheme 7. Schematic illustration of organic amine-functionalized GO carbocatalysis.

The successful anchoring of organic amine groups onto GO surface was achieved by the Henry reaction between benzaldehyde and nitromethane to give the resulting products through nitroaldol addition and dehydration steps in the presence of different types of catalytic systems (Table **1**).

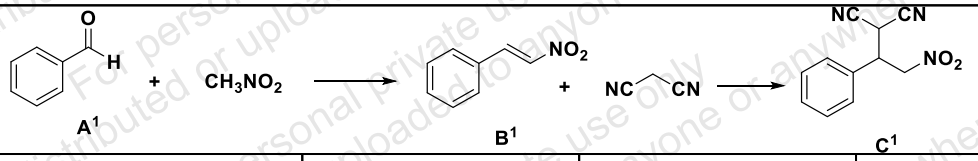


Table 1. Different catalysts in henry reaction.

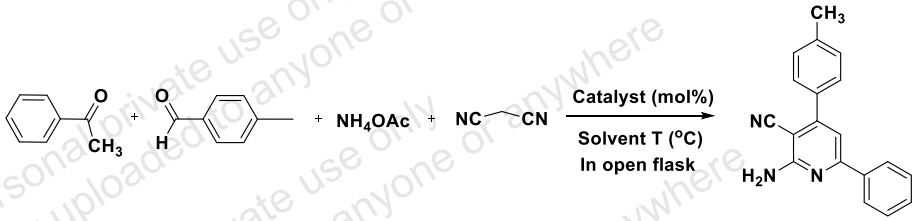
Carbocatalyst	Conversion of A (%)	Conversion to B (%)	Yield of C (%)
GO[2]	0	0	0
AP-GO	90	90	0
MAP-GO	91	76	15
DMAP-GO	84	53	31
PROPYLAMINE	39	39	0
GO+PROPYLAMINE	22	22	0
AP-GO-A[3]	13	13	0
AP-GO-B[4]	36	36	0

Interestingly, the catalytic reactions do not work with GO alone, but the GO-supported organic amines advanced to high conversion of products, showing that organic amines are important active species. The capability of the AP-GO catalyst among others to promote the one-pot Henry-Michael reaction is described in Table **2**. Initially, the carboxylic acids in the edges of GO activate the carbonyl group of benzaldehyde through hydrogen bonding, while the primary amines on the basal planes of GO attack the activated benzaldehyde to form the imine intermediates by the elimination of the water molecule. Eventually, nitromethane attacks this imine in the presence of carboxylic acids by following the elimination of amine species to generate *trans-β*-nitrostyrene. Finally, carboxylic acid activates *trans-β*-nitrostyrene again, to yield the targeted products as Michael adducts [63].

Table 2. Influence of different carbocatalysts in one-pot Henry-Michael reaction.



A^1 B^1 C^1

Carbocatalyst	Conversion of A^1 (%)	Conversion to B^1 (%)	Yield of C^1 (%)
AP-GO	90	97	87
Propylamine	39	49	19
AP-AC	53	58	31
AS-SBA-15	38	40	15
AP-GO-M[b]	34	39	13

Reaction conditions: 0.306 mL of benzaldehyde (3.0 mmol), 6.0 mL of nitromethane, 0.228 of malononitrile (3.6 mmol), a catalyst containing 0.075 mmol nitrogen species, 12 h. [b]Added 3.0 mL of methanol

Even though GO is inexpensive and has numerous remarkable mechanical and electronic properties, easy recovery, and metal-free reactivity from the reaction mixtures, the properties of GO have been relatively less explored as an oxidant or catalyst for facilitating various organic transformations. Eco-friendly synthesis of 2-amino-3-cyanopyridines *via* a GO catalyzed four-component condensation was studied [63] and the catalytic efficiency of GO over other catalysts is compared in Table **3**.

Table 3. A comparative analysis on the efficiency of carabocatalyst (GO) over other catalysts.

Entry	Catalyst (Mol %)	Reaction Conditions[1]	Time, h	Yield[2] (%)
1[3]	-	H_2O, 80°C	24	<10

3.3. Hydrogenation Reaction

With regard to stability and safety issues associated with graphene oxide, when the compound is contaminated with potassium salts, its thermal stability is decreased. These potassium salts are obtained as GO synthesis products. These compounds are extremely flammable and unstable, therefore, a small spark is sufficient to burn down the entire GO film, resulting in a disastrous explosion. Since the compound's thermal instability in the presence of salts (by GO synthesis products) was observed, it was necessary to purify the GO material to prevent a fire hazard. In two phases, an acid wash proved to be a successful purification tool because it suppresses gelation, which is one of the major factors hindering purification. Furthermore, the energy produced from GO's self-propagating domino reactions can be used to generate other materials based on graphene that have high activity [64].

Among all the relevant graphene catalytic operations, its use as a composite photocatalyst for organic pollutant degradation is socially important. Graphene

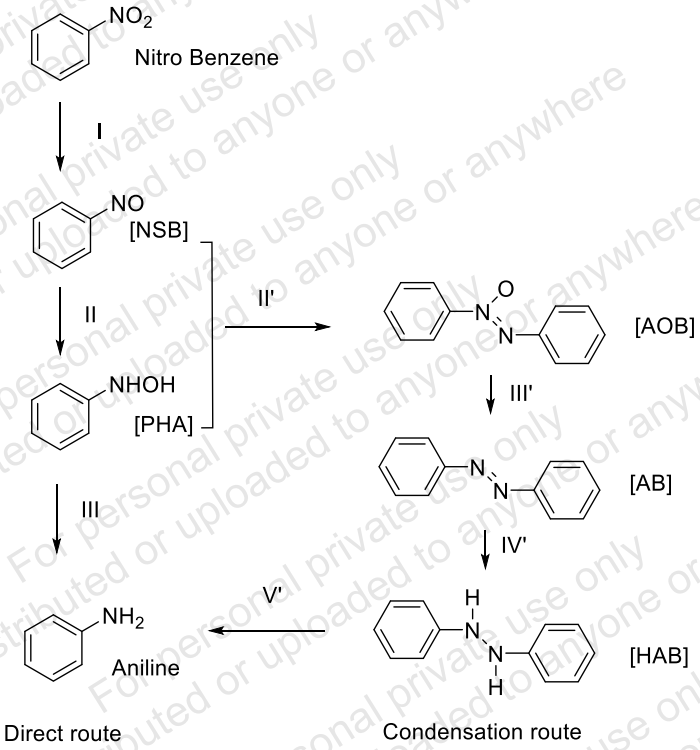
has a honeycomb-like structure with sp^2 hybridized carbon arranged like a sheet. By chemically modifying the graphene, its surface properties like chemical adsorption, transparency, and conductivity will improve, which enhances its use as a composite material. Photocatalysts like TiO_2 can be chemically bonded to graphene by a one-step hydrothermal reaction. P25 is a TiO_2 photocatalyst that is bonded to graphene and can be used for the photodegradation of dyes. P25-Graphene photocatalyst possesses good absorptivity of dyes, a wide range of light absorption, and also charge separation properties, making it different and more efficient than normal TiO_2. Due to its giant 2-D planar structure, the improved activity of the P25-Graphene photocatalyst over normal P25 and other photocatalysts provided a better surface for dye adsorption and also separation charge [65].

Studies show that peroxymonosulfate (PMS) can be effectively activated by chemically reduced graphene oxide to produce active sulfate radicals, which is a powerful oxidizing species with a high oxidizing potential having enough potential to decompose various aqueous contaminants. In comparison with graphite powder (GP), graphene oxide (GO), activated carbon (AC), and multiwall carbon nanotube (MWCNT), graphene exhibits a higher activity. It was demonstrated that graphene catalysis is better than that of Co_3O_4 in the degradation of 2,4-dichlorophenol (DCP), phenol, and methylene blue (MB) in water, which is an efficient system for ecological remediation.

The activation of peroxy-monosulfate by graphene is more like those in oxidative dehydrogenation (ODH) and dehydrogenation (DH) reactions, in the presence of nanocarbon (Lewis base). The reduction of GO hydrothermally tunes the surface acidity/alkalinity by removing the oxygen moieties. By modifying the surface acidity of GO to alkaline by ammonia solution, the activity of graphene in the initiation of PMS improves significantly [66].

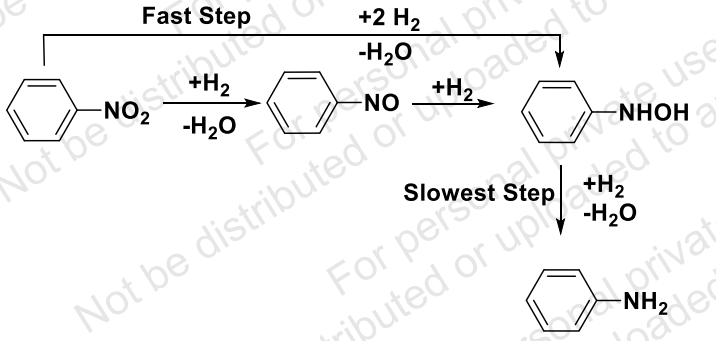
The sp^2 carbon atoms are placed in a hexagonal cell as a conjugated device in the case of a basal plane in perfect graphene. The curvature of stacked graphene layers and edge defects create non-six carbon rings. Two kinds of edges, zigzag and armchair, are created when C-C σ bonds are broken. The localized state at the zigzag edge means that their π electrons are not limited to edge carbons, hence the chemical activity is increased. The zigzag edges of reduced graphene oxides derived from chemical treatment hold a small number of oxygen-containing groups, and the remaining groups have a higher intrinsic activity than those at the end of the flat surface. Chemically reduced graphene oxide at zigzag edges hold a very small number of oxygen groups, and the remaining groups have a significantly higher intrinsic activity than those at the end of the flat surface.

Oxygen functional surface species, such as ketone (C=O) groups, are abundant and have a great deal to organize the redox phase.



PMS (HSO_5^-) is capable of activating graphene to yield two different types of sulfate radicals ($SO_4^{\bullet-}$ and $SO_5^{\bullet-}$). The former radical exhibits a higher oxidative potential value (2.5−3.1 V) and plays a vital role in phenol degradation. This reaction pathway is accompanied with the observations that the operation of different carbons follows the order: graphene > MWCNT > GP > GO, matching to the density of the graphite defects, (b) the action is closely related to the loading of the catalyst, (c) the influence of temperature is less which reflects the character of the graphene carrier, and (d) the similar catalysis analogs applicable to nanocarbons. The activity of graphene is higher than other carbon allotropes (GP, AC, MWCNT, and GO), and then it is on par with the activity of popular transition metal oxides.

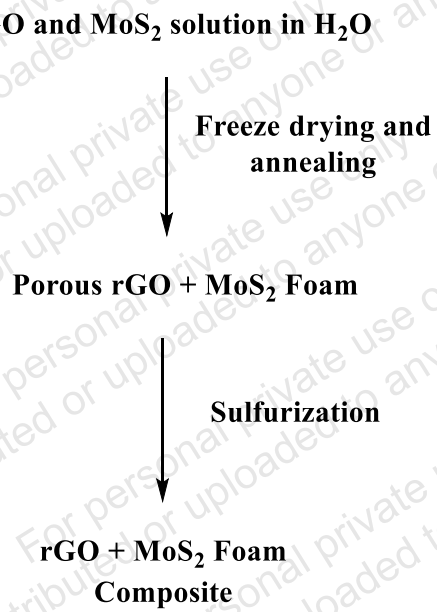
Moreover, hydrogenation reactions of nitroarenes by reduced graphene oxide (RGO)-supported platinum (Pt) catalyst derived from the reduction of ethylene glycol (EG) and its characterization study demonstrated that EG as a reductant exhibits better advantages than the extensively used hydrated hydrazine to produce Pt nanoparticles that are small-sized and monodispersed on the entire surface of RGO. The results reveal that the yields of aniline over the Pt/RGO-EG catalyst are much higher than that of active carbon-supported and multi-walled carbon nanotube-based Pt catalysts. When the reaction temperature was changed to 20°C, the catalytic activity of Pt/RGO-EG was enhanced to 1138.3 mol (mol-Pt min), which proved to be extremely fruitful for the hydrogenation of nitroarene derivatives. The peculiar catalytic behavior of Pt/RGO-EG can be attributed to the well-scattered Pt clusters on the RGO sheets and the homogeneously dispersed Pt/RGO-EG in the reaction mixture. Thus, it is evident that RGO plays a vital role as a support to the catalyst and it is a better promoter than AC and MWCNT. Furthermore, Pt/RGO-EG appears to be a promisingly active and stable catalyst for the hydrogenation of NB (Scheme **8** and Scheme **9**).



The distinctive catalytic operation and simple fabrication process of GO and GO-based composites have the notable ability as heterogeneous catalysis [67].

The hydrothermal treatment of a mixed aqueous precursor solution of $PdCl_4^{2-}$, carbon nanotube (CNT), and GO, as well as the simultaneous spontaneous redox reaction between $PdCl_4^{2-}$ and CNTGO hybrid, resulted in the formation of a 3D macroscopic Pd-CNT-rGO hydrogel. The resulting Pd-CNT-rGO bifunctional nanocatalyst has a large surface area and excellent durability, and thus exhibits remarkably high and stable catalytic activity toward p-nitrophenol reduction, with 100 percent conversion in only 30s. The proposed simple synthetic route and

designed bifunctional catalysts will serve as a universal platform for the fabrication of nano-catalysts that can be used in a variety of catalysis, environmental protection, energy storage, drug delivery, chemical and biological sensing, and other applications [68].



Scheme 8. Mechanistic steps for the hydrogenation of NB.

Scheme 9. Proposed mechanism for the hydrogenation of NB over Pt/RGO-EG catalyst.

Song *et.al.* reported the effect of capping agents on the catalytic function of rGO for redox reactions using nitrogen-containing surface modifiers with distinctly

different chemical structures, such as poly (diallyl dimethylammonium chloride), cetyltrimethylammonium chloride, and poly (allylamine hydrochloride), which can endow rGO with improved suspension stability. The reduction of graphene oxide with hydrazine in the presence of capping agents resulted in the facile preparation of functionalized rGOs. The results of model redox reactions, such as 4-nitrophenol and ferricyanide reduction reactions, catalyzed by functionalized rGOs, confirmed that the way capping agents functionalize rGO, which is highly correlated with their chemical structure, has a significant impact on overall reaction kinetics, such as induction time, reduction rate, total reaction time, and reaction order. This strongly shows that careful capping agent selection is essential for fully exploiting rGO's catalytic function and therefore designing innovative rGO-based non-metallic catalysts with controlled reaction kinetics [69].

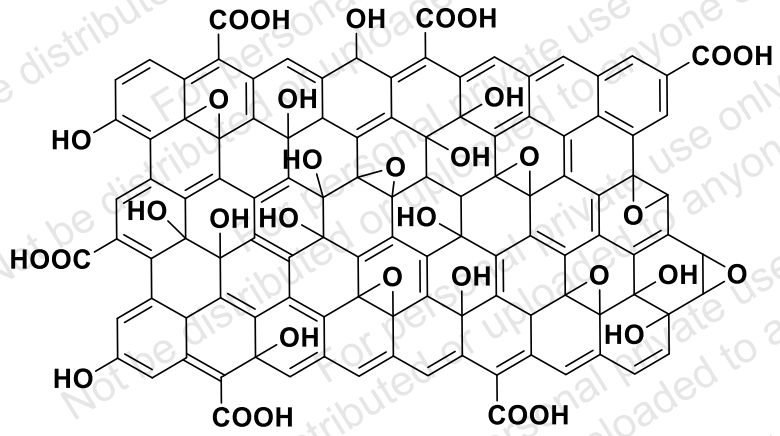
Scheme 10. Procedure of *in situ* growth of rGO supported MoS_2 with high defect density by sulfurization.

Joyner *et. al*. outlined a chemical vapor deposition (CVD) method for growing MoS_2 structures by sulfurizing rGO supported MoO_2 particles. On the basal plane of rGO supported MoS_2 structures, this approach created various morphologies of MoS_2 with large edges and high defect densities, which are considered active sites for hydrogen evolution reactions (HER) catalysis. Furthermore, MoS_2 nanostructures on the surface of the porous rGO network exhibit strong physical interactions, such as van der Waals and π−π interactions between MoS_2 and rGO. As a result of these features, the HER catalyst has been enhanced. With the duration of the sulfurization was 30 min, the 1rGO- 2MoS_2 composition provided

the lowest onset potential of -197 mV. Theoretical calculations show that defects on MoS_2's basal plane do indeed increase catalytic activity, resulting in more active sites. Due to alternative geometries other than triangle structures take longer to saturate the interactions with hydrogen atoms, having alternative MoS_2 geometries allows the system to be active for longer. According to the calculations, having MoS_2 crystals with diverse geometries and defects is favorable for hydrogen catalytic activity because the varied geometries allow the system to remain active for longer periods and the defects increase the number of active sites accessible for hydrogen interactions (Scheme **10**) [70].

Graphene doped with a heteroatom such as oxygen, nitrogen, boron, sulfur, and phosphorus yields a wide range of metal-free organocatalysts carrying improved catalytic performance. In this effort, Jiangbo Xi *et al*. synthesized an N and P-double-doped graphene (NPG) carbocatalyst by microwave-exfoliated graphite (MEG) in presence of hexachlorocyclotriphosphazene (HCCP) in a facile way, which in turn was used as N as well as a P source. This NPG showed a wonderful catalytic activity towards reduction reactions of nitroarenes, furthermore, excellent stability, selectivity, and recyclability [71].

3.4. Aza-Michael Addition



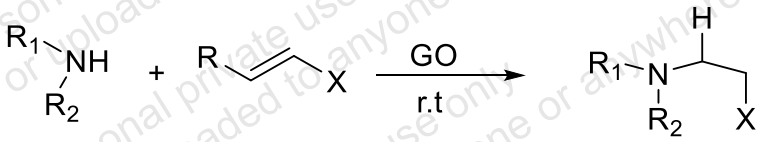


Fig. (1). A schematic design of graphene oxide (single sheet) showing active oxygen groups.

Oxygen-containing graphene oxide (GO) mainly functions as a precursor to the reduced graphene oxide. Various solvents including ionic liquids, water, and aprotic organic solvents, like dimethyl sulfoxide (DMSO), have been used as reaction media in the dehydration of carbohydrates to HMF. Further, ionic liquids are capable of solvents in terms of high selectivity in biomass conversion. For the

dehydration of fructose, graphene oxide can be an efficient carbocatalyst in the presence of isopropanol. Also, GO has been employed under various experimental conditions including strongly acidic and ultrasonic conditions [72]. The arrangement of new carbon-heteroatom bonds through *aza*-Michael expansion is a notable change in organic chemistry, which is of biological significance through active nitrogen-containing molecules, chiral auxiliaries, natural products, and antibiotics. The presence of oxygen-carrying functionalities in graphene oxide (Fig. **1**) facilitates hydrophilicity and allows dispersion in water and further polar solvents. The catalytic potential of graphene oxide nano-sheets was examined for the Aza-Michael addition reaction, as shown in Scheme **11**.

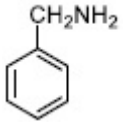
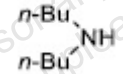
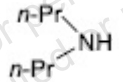
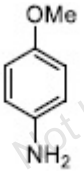
R_2= Et, n-Bu, n-Pr, Bz
X = CN, $CONH_2$, $COOCH_3$









Scheme 11. The catalytic Aza-Michael addition reaction by GO.

Further reaction scope was extended towards aromatic amines, such as aniline and *p*-anisidine, and was found to be less reactive and afforded moderate product yield in longer reaction times as given in Table **4** [73].

Table 4. Graphene oxide catalyzed aza-Michael addition of amines to α,β-unsaturated compounds.

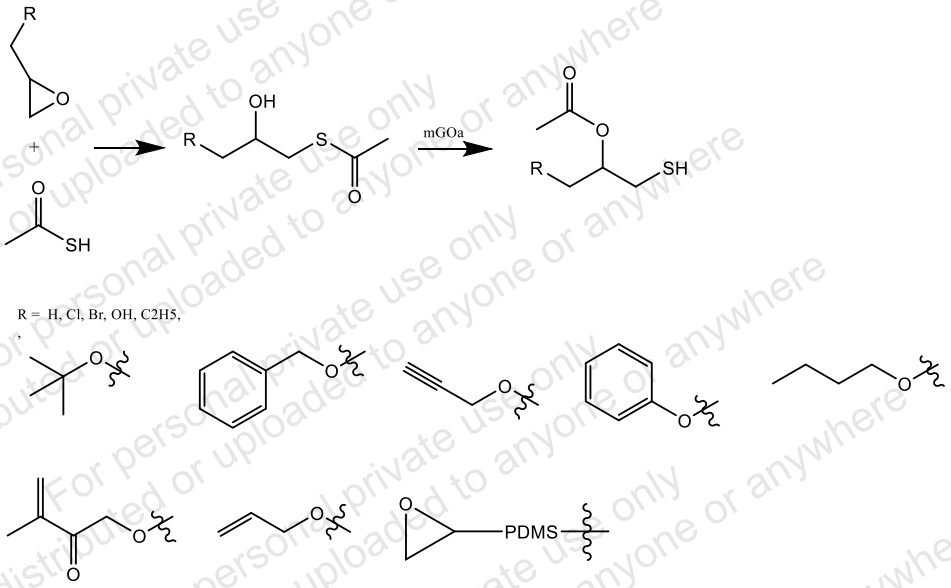
3.5. Dehydration-Hydrothiolation Reactions

To optimize the catalytic activity and observing the yields of the products, various combinations of the reactants were used under varied conditions like changing the amount of catalyst, time, temperature, and different aryl and alky groups. Thioethers can be utilized for synthesizing various biologically vital molecules. It was observed that the reactions with both long-chain and alicyclic thiols were reported (Scheme **12**). The electron-withdrawing group enhances dehydration-hydrothiolation reactions.

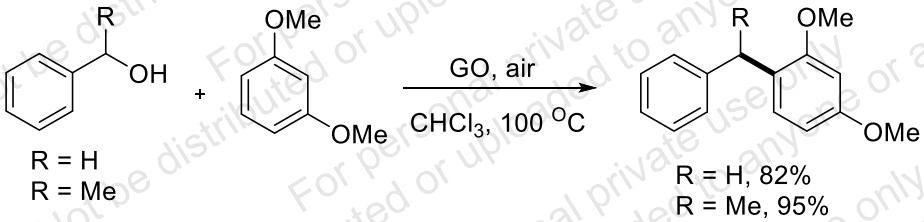
Not be distributed or uploaded to anyone or anywhere For personal private use only

Scheme 12. Graphene oxide-catalyzed dehydration and hydrothiolation.



By this method, the catalyst can be retrieved from the product and can be reused at least 4-5 times without losing the catalytic activity. It was observed from the FT-IR spectrum of the GO catalyst and the GO's functional groups were not at all affected even after several cycles of catalytic reactions and they retained their functionality [74].

Peng *et. al*. developed a three-dimensional monolith of neat GO aerogel as a fixed-bed carbocatalyst for the synthesis of thiol compounds (Scheme **13**), demonstrating the advantages of ultrafast catalytic speed (5-8 h), high selectivity (100%), high yields (near 100%), easy product isolation, and long-life recyclability (> 18 times). For the first time, thiol compounds with halogen and hydroxyl functional groups that cannot be produced using conventional catalysts have been reported. The effective catalysis mechanism is primarily attributed to the protonic functional groups, ultra large size, and unpaired electrons of GO, as well as the "cage effect" in nanoscale constrained areas of aerogel cells, according to control experiments [75].



3.6. Friedel-Crafts Alkylation

The carbonyl functional sites in graphene can also be used as active sites for chemical reactions. The developed carbocatalysts are one without pH adjusted film (G1 film) and another pH adjusted film using ammonia (G2 film). Also, it was noticed that AA (L-ascorbic acid) plays a vital role in the preparation of carbocatalyst. The pH-mediated carbocatalyst enhances electrostatic repulsive interactions and it was observed that the pH and its effect can be seen only during

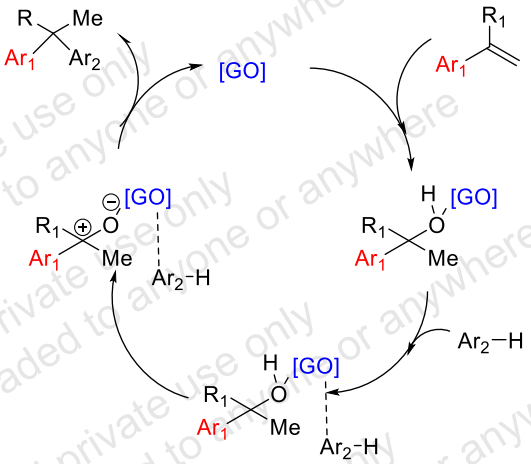
carbocatalyst formation with AA and after the reaction, the active edges are exposed (Scheme **14**) [76].

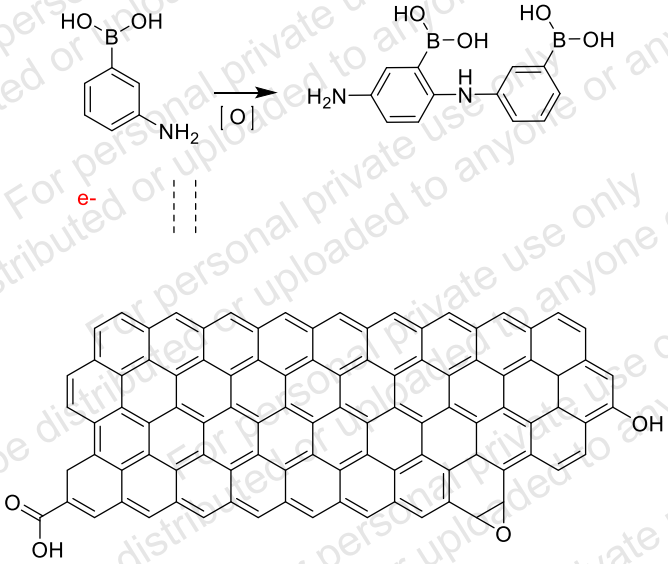
Scheme 13. Acetyl migration reaction of latent thiol compounds into thiol compounds catalyzed by mGO fixed-bed.

Scheme 14. GO-catalyzed direct Friedel-Crafts alkylation of arenes to alcohols.

Alkylation of arenes to diarylmethanes catalyzed by graphenes has been reported as shown in Fig. (**2**). The activation of the reactants on the catalyst surface is due to the active edges of aromatic polar functional groups on the surface of graphene.

It was observed that RGO can be used as a very effective catalyst in electrochemical and in-situ polymerization reactions of ABA whereas the GO can be used as an active catalyst for in-situ polymerization reaction of ABA only and in the case of electrochemical polymerization RGO, it enhances the formation of ABA rather than GO. Whereas in the case of *in-situ* both the carbocatalysts exhibits good efficacy and the reaction of polymerization depends on the concentration of monomer and oxidants on the surfaces (Scheme **15**) [77].





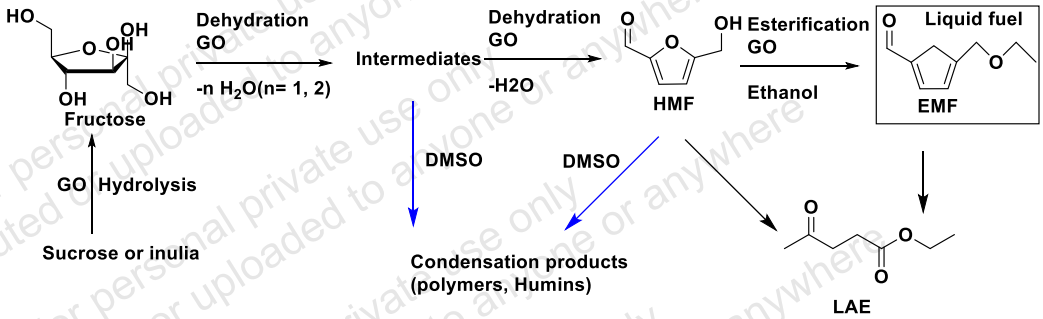


Fig. (2). Reaction pathway for the GO-catalysed alkylation of arenes.

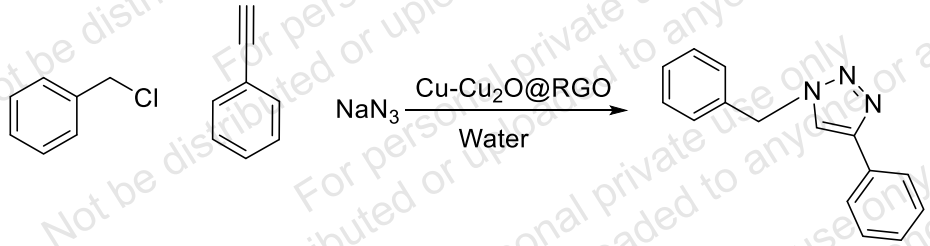
Scheme 15. Schematic illustration of the electron-withdrawing process from the RGO Substrate to ABA.

The preparation of graphene oxide (GO) carbocatalyst by the Hummers method is well-known. A graphite's oxidation in presence of strong acidic conditions and strong oxidizing agents gives GO. This method enhances the oxygen-functionalized groups on the GO surface. GO is can be retrieved back effectively after the reaction process and it is also be used as an acid catalyst for opening the ring of epoxides. The conversion of carbohydrates to 5-ethoxy methyl furfural (EMF) has been reported. The formation of 5-hydroxymethylfurfural (HMF) on etherification with ethanol and GO catalyst gives EMF. The yield of EMF is

affected by the loading capacity on the carbocatalyst surface and the temperature. This conversion of bio-mass compounds to useful chemicals using GO as a catalyst would open up a wide area of research (Scheme **16**) [78].

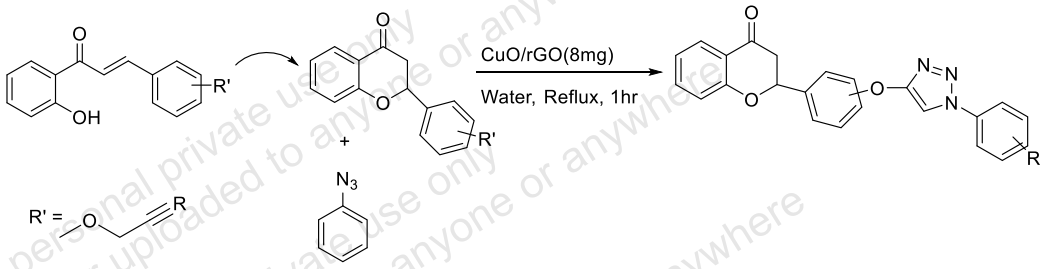
Scheme 16. The conversion of carbohydrates to EMF catalyzed by GO.



3.7. Other Useful Reactions

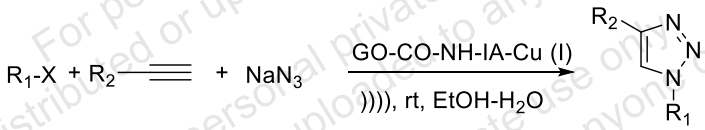
In a range of applications, graphene-based materials with hierarchical structures and multifunctionality have roused attention. Yang *et al*. reported a simple, yet universal, the method for making graphene-based composite cellular foams (GCCFs) using a mixture of redox reactions. Cationic polymers facilitate assembly and biomimetic mineralization. Cationic polymers (*e.g*., polyethyleneimine, lysozyme, *etc*.) could not only decrease and assemble graphene oxide (GO) into cellular foams, but they could also induce mineralization, allowing the formation of inorganic nanoparticles (silica, titania, silver, and so on). The GCCFs have a highly porous structure and adequate structural stability, with nanoparticles evenly distributed on the surface of the reduced GO. A series of GCCFs are synthesized by varying polymer/inorganic pairs, which exhibit significantly improved catalytic performance in enzyme catalysis, heterogeneous chemical catalysis, and photocatalysis when compared to nanoparticulate catalysts [79].

Furthermore, graphene oxide is good support for immobilizing lipase in an organic solvent for catalysis. Lipase was immobilized using carboxyl functionalized graphene oxide (GO-COOH). To characterize lipase immobilization, FTIR, UV-vis, and XPS spectra were measured. The immobilized lipase retains 80% of the hydrolytic activity of the native lipase at the optimum temperature of 40 °C. The catalysis efficiency of the immobilized lipase is 1.6 times that of native lipase. when catalyzing the enantioselective reaction in the organic solvent heptane at 50 °C (optimal), and the immobilized lipase retains the native lipase's selectivity [80].



Using a spray-drying approach, Z. Xu *et. al*. developed hollow reduced graphene oxide microspheres containing well-distributed Fe_2O_3 nanoparticles (Fe-rGOS). L-ascorbic acid was used to decrease graphite oxide (GO) and increase electron transfer velocity. The *in situ* Fe_2O_3 nanoparticles with a mean size of 5-10 nm were uniformly deposited on rGO support due to the L-ascorbic acid and spray-drying procedure, and the rGO migrated to the drop's surface to form microspheres. The well-dispersed nanoparticles not only generated more active sites and interface contact, which improved catalyst stability but also acted as pillars between the rGO layers, resulting in a mesoporous structure. The formed mesoporous frameworks significantly improved mass transfer, resulting in significantly higher catalytic efficiency. As a result, the prepared Fe-rGOS demonstrated remarkable photocatalytic activity across a wide pH range, as well as superior recyclability with low iron ion leaching [81].

The detailed syntheses of miscellaneous heterocyclic compounds catalyzed by graphene-based carbocatalysts were very well-reviewed [76]. The Cu–Cu_2O@RGO nanocomposite was studied as a promising reusable catalyst in a multicomponent reaction of halides and sodium azide with terminal alkynes for the synthesis of 1,4-disubstituted 1,2,3-triazoles [82] (Scheme **17**). Strikingly, the merging of RGO and Cu–Cu_2O nanocomposite prevents the aggregation of RGO but also enhances the improved stability and catalytic performance of the metal nanoparticles loaded at RGO.



Scheme 17. Cu-Cu_2O@RGO catalyzed synthesis of triazoles by a facile cycloaddition.

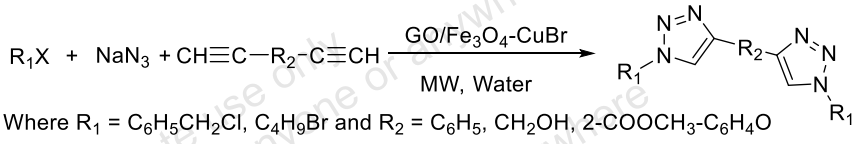
Gupta *et al*. [83] described an effective and viable click reaction for the one-pot synthesis of hybrid molecules containing flavanone with triazole by amalgamating Michael addition using copper oxide/reduced graphene oxide (CuO/rGO) nanocomposite (Scheme **18**). A comparison of CuO/rGO with other catalysts was carried out.

Scheme 18. CuO/rGO catalyzed synthesis of flavanone containing triazole derivatives.

A three-component reaction of sodium azide and alkyl halides in the presence of terminal alkynes was reported [84] by using functionalized graphene oxide copper(I) complex (GO–NH–IA–Cu(I)) under ultrasonic irradiation at room temperature (Scheme **19**).

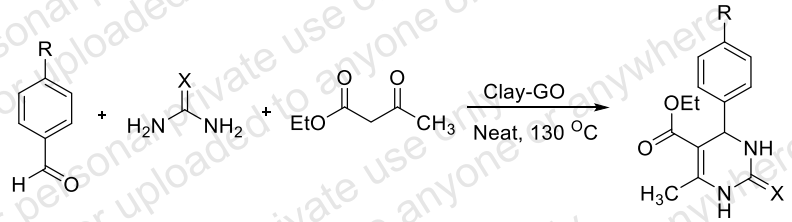
Where X = Cl, Br, I; R_1 = alkyl, benzyl, cinnamyl and R_2 = Ph, CH_3-Ph, $CH_3CH_2CH_3$

Scheme 19. Catalytic synthesis of triazole derivatives by functionalized graphene oxide-Cu(I) complex.



In addition to this, studies on the catalytic synthesis of β-hydroxy-1,2,3-triazole derivatives from aryl-substituted epoxide, phenylacetylene, and sodium azide by GO@polytriazole–Cu (GO@PTA–Cu) mediated by ultrasound irradiation were carried out [85] (Scheme **20**).

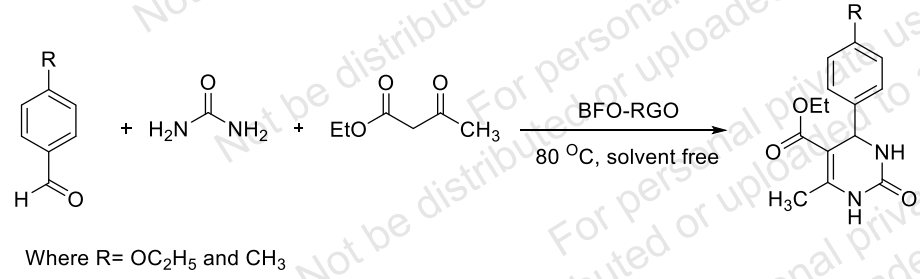
Where Ph = C_6H_5, 4-CH_3-C_6H_5 and $C_6H_5OCH_2$



Scheme 20. Catalytic synthesis of β-hydroxy-1,2,3-triazole derivatives using GO@polytriazole-Cu-catalyst.

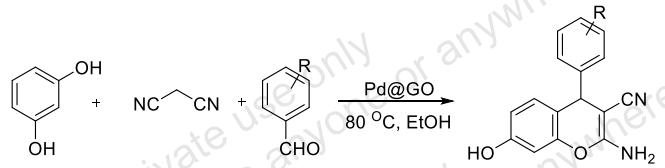
Furthermore, Xiong *et al*. [86] used GO/Fe_3O_4–CuBr catalyst was employed as a special semi-heterogeneous catalyst for the multicomponent reaction of azide, alkyl halide, and alkyne through 1,3-dipolar cycloaddition by microwave irradiation to yield mono/bis-1,2,3-triazoles (Scheme **21**).

Scheme 21. Microwave-assisted catalytic synthesis of substituted-1,2,3-triazoles using GO/Fe_3O_4-CuBr.



Narayanan *et al*. [87] reported neat, effective, and simple Biginelli reactions of aryl aldehyde, ethyl acetoacetate, and urea in the presence of clay-graphene oxide as recyclable nanocatalyst (montmorillonite clay–GO) (Scheme **22**).

Scheme 22. Clay-GO nanocomposite catalyzed synthesis of 3,4-dihydropyrimidinone.



Similarly, Moitra *et al*. [88] reported a solvent-free preparation of 3,4-dihydropyrimidin-2(1H)-ones (Scheme **23**) in presence of $BiFeO_3$ nanowire-reduced graphene oxide (BFO-RGO) nanocatalyst. Furthermore, Akocak *et al*. [89] established an eco-friendly method for the synthesis of 2-amino--H-chromene derivatives *via* condensation of resorcinol, malononitrile, and diverse aromatic aldehydes in the presence of palladium nanoparticles loaded on graphene oxide (Pd@GO) (Scheme **24**).

Investigations were carried out on the usage of magnetically separable nanocatalyst, Fe_3O_4-supported-N-pyridin-4-amine-grafted graphene oxide for the synthesis of chromenes from a multicomponent reaction of malononitrile, dimedone, and aryl aldehydes [90] (Scheme **25**).

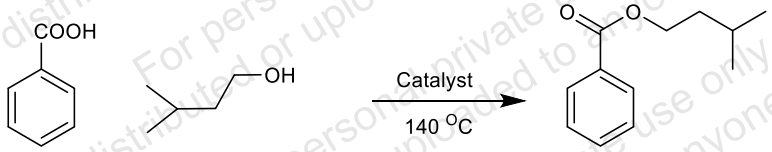
Kausar *et al*. [95] reported a metal-free carbocatalyst to prepare a variety of dibenzo [1, 4] diazepine scaffolds from *o*-phenylene diamine, aldehydes, or ketones, and 1,3-diketo compounds (Scheme **30**) employing graphene oxide (GO) nanosheets as carbocatalyst to producedibenzo [1, 4]diazepines.



Several carbocatalysts have been examined for PMS activation for the oxidation of phenol in an aqueous medium. In absence of carbocatalyst, the PMS could unable to generate activated radicals for phenol degradation. In parallel, without PMS addition, hardly 4% of phenol was removed because of adsorption on the NG-700 surface.

Where R_1 = H, CH_3 and R_2 = aryl, heteroaryl, alkyl and benzoyl

Scheme 30. GO nanosheet catalyzed preparation of dibenzo [1, 4]diazepines.

The GO and RGO catalysts usually are not that stable or soluble in an aqueous medium and there is a need for optimization of this catalytic activity of GO and RGO by incorporating a polymer PSSS (poly(sodium 4-styrene sulfonate)) which enhances the dispersion of this catalyst in an aqueous medium. PSSS is water-soluble which is incorporated into the graphene surface through a radical initiator (ATRP). ATRP use is that it facilitates the incorporation of PSSS on the graphene surface. Once this GO-g-PSSS catalyst is ready, it can be used as the catalyst for various chemical reactions. In the same way, RGO-*g*-PSSS is also improvised which also helps in the synthesis of isoamyl benzoate (Scheme **31**). Also, the PSSS is pH-sensitive, such that the introduction of any drugs to the surface can be released concerning the drug's response to the change of pH. This method is used to improvise the dispersion of graphene oxide and reduced graphene oxide in the aqueous solution [96].

Scheme 31. Preparation of isoamyl benzoate.

CONCLUSION AND FUTURE PROSPECTS

With the development of several advanced catalytic systems for diverse chemical processes, carbocatalysts are one of the efficient classes of heterogeneous materials of high industrial significance. Several GO based catalysts employed for a wide range of organic transformations reported in the past are summarised in Table **5**. Owing to their remarkable properties, including high intrinsic mobility, large specific surface area, excellent electrical conductivity, high thermal conductivity, ease of preparation, chemical inertness, and facile functionalization, graphene-based materials have become promising recyclable and sustainable catalysts. In the light of this, the present chapter highlights the preparation of different types of carbocatalysts, the possible reaction mechanisms, and multi-

component organic transformations. Various graphene-based materials (graphene oxide/ reduced graphene oxide/ their nanosheets/metal-nanoparticles grafted on graphene/ functionalized graphene oxide/ quantum dots/ graphene oxide-spinel composites) have been employed for the preparation of a variety of heterocyclic molecules. Relatively faster synthesis of thiophenes, triazoles, aziridines, tetrazoles, pyrazoles, imidazoles, furans, oxindoles, pyrimidines, chromenes, coumarins, quinazolines, oxazoles, quinoxalines, xanthenes, pyridines, and diazepines was reported in good to excellent yields. The high catalytic activity of graphene-based catalysts is mainly attributed to the incorporation of Brønsted acid sites and/ or Lewis acid-base centers in these carbon materials, accompanied by π–π stacking and electrostatic interactions through the increased adsorption of reactants. Additionally, the advantage of these carbocatalysts is that they are very easy to recover by filtration/centrifugation and/or magnetic decantation. Moreover, the low catalyst loading, renewability, and solvent-free conditions make them very special catalytic systems concerning sustainability and environmentally benign processes. The major limitations of these graphene-based carbocatalysts are the identification of the actual reactive sites of graphene oxide, functionalities, defects, and edges. These problems can be overcome when suitable models are designed describing the structure of graphene-based materials at the molecular level. Still, better graphene-based carbocatalysts need to be developed with less complexity and cost-effectiveness by doping/ double doping with B/ B-N/ P-N and other appropriate dopants, as evident in the facile activation of molecular hydrogen at the periphery and holes with zigzag edges. This will be a promising field for future applications of catalysis by graphene-based materials.

Table 5. Previously reported graphene oxide catalyzed reactions.

S.no	Catalyst	Reaction	Reference
1	rGO	Oxidation of methylene blue, phenol, 2,4-dichlorophenol by H_2O_2	[97]
2	(B, N) doped rGO	Oxidation of phenol by peroxymonosulfate or H_2O_2	[98]
3	rGO	Hydrogenation	[99-100]
4	rGO or N-rGO	Reduction of 4-nitrophenol to 4-aminophenol by $NaBH_4$	[101-102]
5	rGO	Synthesis of dipyrromethene, calix [4] pyrrole and 5-substituted 1H-tetrazoles	[103-104]
6	rGO	Thermal dehydrogenation and re-hydrogenation of $LiBH_4$	[105]
7	rGO-NEt_3	Hydrolysis of ethyl acetate	[106]
8	rGO-PAMAM	Knoevenagel condensation	[107]
9	rGO-SO_3H	Dehydration of xylose to furfural, Esterification and transesterification, pechmann reaction, hydration of propylene oxide	[108-110]

(Table 5) cont.....

10	rGO-poly(styrene sulfonic acid)	Synthesis of isoamyl benzoate	[111]
11	rGO-Ar-SO_3H	Hydrolysis of ethyl acetate, synthesis of xanthenes and benzoxanthenes	[112-113]
12	GO	Aerobic oxidation of alcohols	[114-115]
13	GO	Dehydrogenation of propane to propene	[116]
14	GO	Aerobic oxidation of SO_2	[117]
15	GO or rGO	Polymerization of 3-aminophenylboronic acid	[118]
16	GO	Ring opening of epoxides	[119]
17	GO	Michael addition reaction	[120]
18	GO	Aza-michael addition of amines to alkenes	[121]
19	GO	Dehydrative esterification of benzyl alcohol	[122]

LIST OF ABBREVIATIONS

AC	Activated Carbon
AA	L-Ascorbic Acid
ABA	Azo Benzoic Acid
ATRP	Atom Transfer Radical Polymerization
ASC	Ascorbic acid
CDG	Chemically derived Graphene
CVD	Chemical Vapour Deposition
DH	Dopamine Hydrochloride
DCP	Dichlorophenol
DH	Dehydrogenation
DMSO	Dimethyl Sulfoxide
EG	Ethyleneglycol
EMF	5-Ethoxy Methyl Furfural
GO	Graphene Oxide
GP	Graphite Powder
GCCF	Graphene Composite Cellular Foam
HMF	5-Hydroxy Methyl Furfural
HCCP	Hexachlorocyclotriphosphazene
HQ	Hydroquinone
HZ	Hydrazine
HER	Hydrogen Evolution Reaction

For personal private use only Not be distributed or uploaded to anyone or anywhere

ME	2-Mercapto Ethanol
MWCNT	Multi Wall Carbon Nanotube
MB	Methylene Blue
MEG	Microwave Exfoliated Graphite
MGN	Metal Graphene Nanocomposite
NPG	N&P double doped Graphene
[(N)G]	N-doped defective Graphene
ODH	Oxidative Dehydrogenation
PMS	Peroxymonosulphate
PSSS	[Poly(Sodium-4-Styrene Sulfonate)]
rGO	Reduced Graphene Oxide
rGO-PAMAM	Poly(amidoamine)-modified Reduced Graphene Oxide
SA-GO	Sulfur Graphene Oxide
TBHP	Tert-Butyl Hydroperoxide
$TMSN_3$	Trimethylsilylazide
TOF	Turn Over Frequency

CHAPTER 9

Oxidation and Reduction Reactions Catalyzed by Graphene Based Catalysts

Chetna Ameta[1,*], **Priyanka Chundawat**[1], **Yogeshwari Vyas**[1], **Reema Agarwal**[1] and **Dharmendra Dharmendra**[1]

Abstract: Graphene has several features, such as charge mobility, high conductivity, and a large specific surface area with a two-dimensional structure. It also has exceptional electrical, mechanical, and thermal properties. Graphene has exceptional mechanical, physical, and chemical properties, which are responsible for the development of efficient graphene-based catalysts for selective organic synthesis. This chapter recapitulates the various applications of graphene-based catalysts in oxidation and reduction reactions. It gives a complete overview of graphene, reduced graphene oxide, functionalized graphene oxide, N-doped graphene oxide, and their catalytic applications in various oxidation and reduction reactions. The previous studies reveal that metal-free GO has many catalytic applications. Owing to its high surface area, graphene oxide has a high adsorption tendency for hydrocarbons, gases, and ions.When reacting with oxygenating functionalities, GO provides several paths for introducing and modifying various functional groups. The large potential is employed for the use of metal-free carbon catalysts to resolve the industrial problems arising from traditional catalysts. Since graphene/GO catalysts are synthesized from environmental-friendly material, their applications in green synthesis should be discovered vigorously. The graphene-based catalysts have several applications. They allow only selective, mild, and highly effective transformations and undergo the synthesis and synthesis in an easy, recyclable, regenerable, and environmentally friendly manner.

Keywords: Graphene, Reduced Graphene Oxide, Functionalized Graphene Oxide, Metal-free Structured Carbon Catalysts, Oxidation and Reduction Reactions, Green Method.

INTRODUCTION

In the last decade, the utilization of nanomaterials as catalysts and supporting catalysts has propagated immensely. More exciting is the fast development in the research on the application of structured carbon nanomaterial in catalysis.

Graphene is composed of a two-dimensional carbon network and it is also used for the synthesis of other carbon materials such as single and multiwalled carbon tubes (1D), fullerenes (0D), and graphite (3D) [1]. All the above-mentioned carbon materials are used as a support system for catalytic active phase and metals, it can also be used as a metal-free catalyst.

Carbon nanomaterials own unique properties, such as electrochemical and chemical stability, the tendency for a high degree of functionalization, and high surface area. In the last few years, extensive studies have been done on single and multi-walled carbon nanotubes to explore their use in catalysis, energy and electronic devices, polymer fillers, biological applications, and drug delivery. In 2004 mechanically exfoliated single-layer graphene sheets were reported.

Graphene-based materials have a huge application in energy storage, photocatalysis, catalysis, solar cells, memory devices, drug delivery, nano circuitry, and sensing platforms [2]. Several unique thermal, electronic, mechanical, and optical properties are owned by pristine graphene, these above properties are different from other forms of carbon. But, pristine graphene has some limitations, such as complex synthesis procedures and poor processability. Graphene oxide, reduced graphene oxide, and chemically modified graphene can be used as alternatives to pristine graphene because they can be easily prepared and processed in large quantity and also they can be easily synthesized, processed and dispersed in water and other organic solvents. However, they have some mechanical and electrical properties which are somehow different from graphene and responsible for disturbance in few applications. Yet, they are the appropriate starting materials for several applications [3].

Pristine graphene has zero bandgap and is a stable and inert material, whereas graphene oxide and reduced graphene oxides are either insulators or semiconductors. Graphene consists of only carbon material, while graphene oxide and reduced graphene oxide contain several organic functional groups which can further undergo modifications. At present main function of GO, graphene, and CMGs (chemically modified Graphene) are to act as supporting materials for catalytically active transition metals. So, we need to find more striking alternatives concerning extended stability, low cost, flexibility, and ecological influence.

The biological grade synthesis processes are highly toxic processes which is a matter of great concern, particularly the leakage of metal from their supports. To solve these problems, heterogenous metal-free catalysts made up of carbon materials [4] and noncarbon materials [5] can be used as an alternative. Over the past two decades, innovation and growth in new forms of carbon like nanotubes,

fullerenes, graphene, and nanofibers have resulted in an emphasis on the development and use of metal-free carbon catalysts. Important applications of CMGs and metal-free graphene oxides are their use in various chemical reactions as green catalysts.

The application of graphene and graphene oxide in catalysis has been discovered recently. Because of their use in battery and fuel cells, these materials have gained much attention already, specially N-doped graphene shows excellent activity for electrocatalytic oxygen reduction reaction (ORR). In this chapter, we will emphasize recent development and synthesis and oxidation and reduction reactions catalyzed by GO, FGO (Functionalized graphene oxide), and heteroatom doped graphene, which does not gain much consideration.

SYNTHESIS OF GRAPHENE/GRAPHENE OXIDE

Graphene

The exfoliation method was used first time for the experimental research of a single atomic layer of graphene. But this synthesis method is not adaptable for producing high-quality graphene on a large scale. The development of graphene sheets from graphite is done by the use of various chemical methods. The solvent used in the chemical method can interrupt the p–p interaction between sheets and result in individual stabilization of graphene [6], another alternative method is the bottom-up method in which, at high-temperature organic precursors are used for the direct growth of graphene [7].

The above methods have a large number of limitations, such as poor solubility, which results in graphitization and an increase in defect sites, and the number of unwanted side reactions. Even with the lots of development in the above alternative techniques, the mechanical exfoliation route is still the best method to produce graphene sheets of good quality.

Graphene Oxide and Reduced Graphene Oxide

Brodie [8], Staudenmeier [9], and Hummers [10] proposed the most common method to prepare to GO. In this method, graphite is oxidized with a strong oxidizing agent and results in samples having the same degree of oxidation. In the last decade, a modified Hummers method has become much more popular because it does not produce hazardous ClO_2 gas, has a short reaction time, and peroxidation steps promote further oxidation.

In Modified Hummers method, oxidization of flake graphite powder takes place, in these method flake graphite powder is mixed with phosphorus peroxide (P_2O_5)

and potassium persulphate ($K_2S_2O_8$) and stirred after the above mixture is dissolved in concentrated sulfuric acid (H_2SO_4). Afterward, the further oxidation of graphite is done by adding a mixture of potassium permanganate ($KMnO_4$) and H_2SO_4 and it is cool down to remove the reaction heat. After that, exfoliation of oxidized graphene is done by sonication, or mechanically it is done by polymers or surface stabilizing solvents [11].

GO is made up of a carbon framework containing a variety of oxygenating functionalities. GO lacks well-defined stoichiometry or uniquely defined structure, and distribution, location, and density of different oxygenate functionalities are defined by the synthesis method and the starting graphite material. Lerf and Klinowski [12] proposed the most acceptable structural model of GO, as shown in Fig. (**1**). This model indicates that and epoxy and hydroxyl groups are present at the basal plane of a GO sheet, and carbonyl groups and carboxylic acid are present at the edges of GO sheets. The above groups disturb the delocalization of p electrons and make graphene oxide electrically insulating. The polarity of the above group and their capability to contribute to hydrogen bonding results in the hydrophilic nature of GO and make it easily soluble in polar solvents or water. The carboxylic acid groups present at the edges of graphene oxide sheet are ionizable in less acidic aqueous solution, and the suspension of GO sheets in polar and aqueous solvents are stabilized by electrostatic repulsion between above-charged groups, and this repulsion is also responsible for the separation of GO sheets.

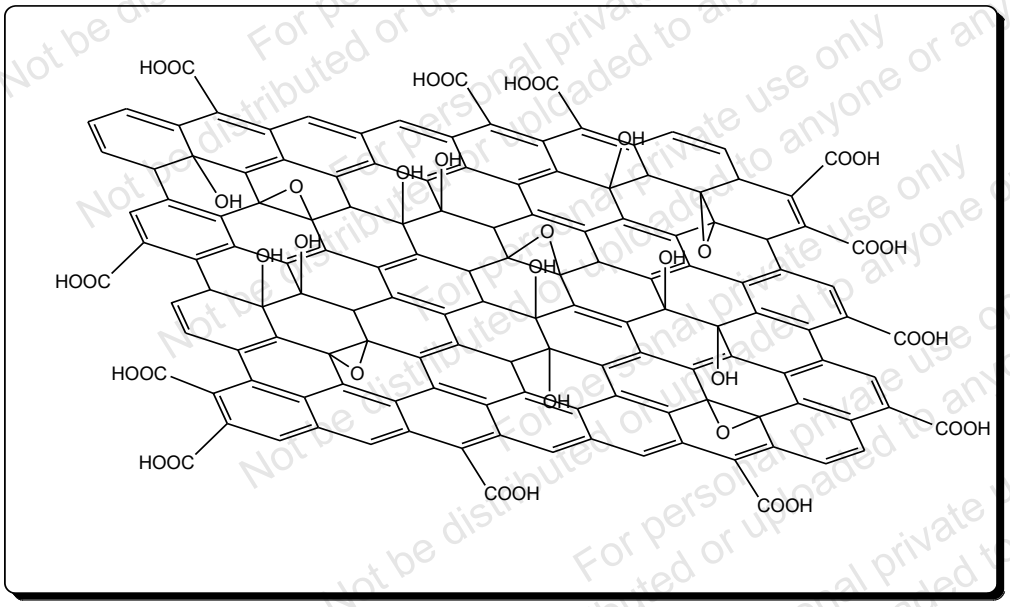

Fig. (1). Proposed structure of graphene oxide (honeycomb graphene lattice).

Few exceptional properties of graphene are retained by the reduction in oxygen functionalities. After reduction GO is signified as reduced graphene oxide, indicating the incomplete reduction. However, at a present complete reduction has not been achieved by researchers. Chemical, thermal and electrochemical methods are the commonly used method for the synthesis of rGO, and all the above methods retain the conjugated p-p bond up to some extent. For the chemical reduction of GO, lithium aluminum hydride is used as a strong reducing agent.

However, lithium aluminum hydride gives dangerous side reactions, so it cannot be used for the reduction of GO. So to avoid the above problems, less reactive chemicals such as hydrazine monohydrate are used for reduction of GO and reduction is also possible in aqueous solvents. Sodium borohydride, hydroquinone, and strong alkaline solutions are some other effective reducing agents employed for the reduction of GO. The main disadvantage associated with the chemical reduction is the incorporation of heteroatom impurities into the basal plane. The heteroatom nitrogen is incorporated into the basal plane by the reacting carbonyl group with hydrazine. This contamination affects the resulting electronic properties.

The ideal condition for effective reduction is achieved at high temperatures especially between 500-1,000°C using a dilute hydrogen atmosphere. Thermal reduction of graphene oxide and reduced graphene oxide is made in an inert atmosphere at a temperature above 500°C. More complete reduction is obtained at very high temperatures up to 1,000°C. This is because of the thermal cracking of C-C and C-O bonds in decarbonylation, dehydration, dehydrogenation, and decarboxylation reactions. Gas produced in reduction reaction is considered a byproduct, consisting of carbon dioxide, carbon monoxide, water, and perhaps hydrogen. Fast production of these gases creates pressure in the graphene oxide layers, which exfoliates the sample.

As the exfoliation process results in a higher surface area of the sample as compared to the area obtained by chemical reduction, it also has some drawbacks, such as it results in huge mass losses (30%) and it produces significant defects, these defects affect the electronic and chemical properties of rGO. These defects formation is controlled by employing successive reduction of chemical and thermal reduction. The third commonly used method for reduction is electrochemical reduction. In the above method, the electrode is prepared by placing a graphene oxide sample on the substrate, and this electrode is immersed in an electrolyte solution. The reduction process is completed by passing a current among a counter electrode and substrate [13]. The major drawback associated with this method is that the large-scale production of rGO is not possible.

Functionalized Graphene Oxide

To get a more adaptable material, various routes have been employed to change the GO surface through a change in a covalent bond. The various route which was employed to discover the functionalized carbon nanotubes can be used for graphene. For GO, numerous information is available that explains the functional group's nature, so the chemical reactions used to convert them into other functional groups have been employed.

Unfortunately, there are no particular techniques available for successful selective transformations, so effective transformation is not possible. However, these transformations are broadly used transformations, and the extensively used conversion reaction of an epoxy group and carboxylic acid are discussed below and also, several effective methods used for the synthesis of catalysts are discussed below. Unlike another organic synthesis, activation of surface carboxylic acid groups is necessary for their transformation. Once the carboxylic acid group gets stimulated, the carbon present in carboxylic acid becomes more susceptible to nucleophilic attack forming the covalent bond with nucleophiles.

Thionyl chloride ($SOCl_2$) [14, 15], 1-ethyl-3-(3-dimethyl aminopropyl) carbodiimide (EDC) or N-(3-dimethyl aminopropyl)-N-ethyl carbodiimide hydrochloride (EDCI) [16 - 19], and N,N-dicyclohexylcarbodiimide (DCC) are the commonly used activation or coupling reagents. Commonly used nucleophiles have a hydroxyl group or an amine that forms an ester and amide bond with graphene oxide and results in the formation of targeted entities on the graphene oxide surface. A ring-opening mechanism is used for the transformation of graphene oxide surface by its reaction with an epoxy group [20], but the above reaction is not much selective. For example, in the reaction of an amine with carboxylic acid, simultaneous aminolysis of epoxide may occur. Another method used for the activation of a carboxylic acid is the solvothermal method [21].

Other methods used to functionalize GO surface are the condensation of methoxy and ethoxy groups with surface hydroxyl group [22]; this is done by using the same method which is employed for fixing molecules on usual heterogeneous supports like Al_2O_3 and SiO_2. The rarely used method, which is the covalent functionalization of the graphitic area of reduced graphene oxide with diazonium salt is done by using a radical mechanism, and is also employed for catalyst synthesis.

N-Doped (Heteroatom-Doped) Graphene

Post-treatment of graphene or GO or in situ growth are generally used methods for the synthesis of heteroatom-doped graphene catalysts. In the last few years, N-

doping has become the most popular subject [23]. In the in-situ growth method, heteroatoms are integrated through the growth procedure by adding in an N-containing reagent, by CVD takes place. The key advantage of the in situ method is that it offers new catalytic properties and it also allows retains the intrinsic physical and chemical properties of pristine graphene. N-doped graphene can be synthesized by CVD by passing a gaseous mixture of CH_4, NH_3, and H_2 in an Ar carrier over a substrate.

The incorporation of nitrogen into graphene aromatic structures can be done by using various forms such as pyrrolic and pyridine nitrogen (Fig. **2**). Solvothermal synthesis processes are another type of in situ method. For example, during the pyrolysis process reaction of lithium nitride undergoes the reaction with tetrachloromethane by using stainless steel autoclave. In the post-treatment method heteroatoms are incorporated by indulging graphene oxide with various compounds by using a physical and chemical method like bypassing NH_3 over graphene oxide at high temperatures or combining graphene oxide with nitrogen sources such as dicyandiamide, melamine, and pyrrole, and then post-treatment method like thermal and chemical reduction is employed. Depending on the experimental details, nitrogen atoms can be merged into graphene oxide in various forms.

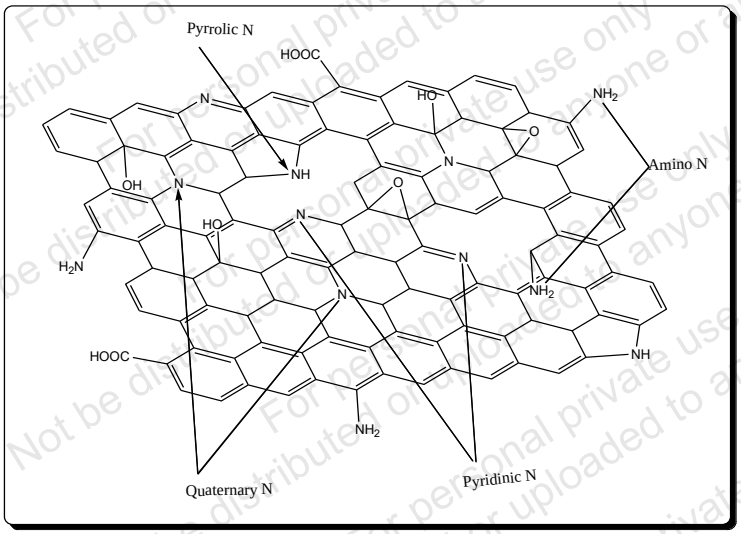

Fig. (2). Schematic illustration of the various forms of 'N' atom incorporation into the graphene structure.

CATALYTIC APPLICATIONS

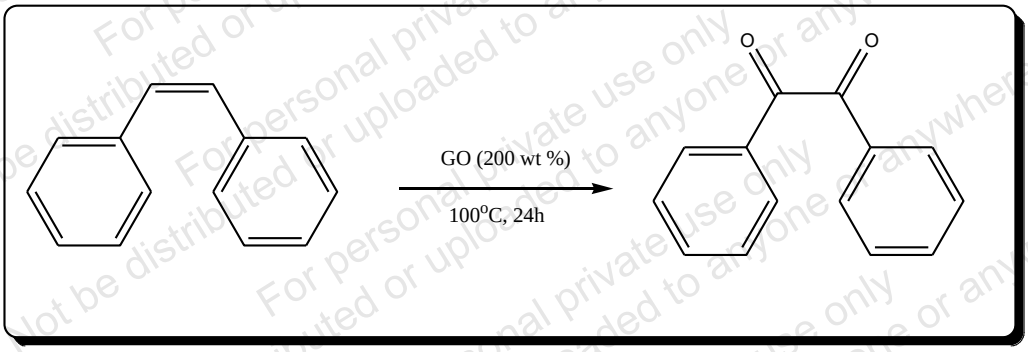
As we already know that carbon and carbon-based materials like graphitic carbon and activated carbon play a very important role in catalysis and the functionalized carbons are generally more selective and active as compared to their

unfunctionalized counterparts. Since, because of heterogeneity of functionalized carbons, the determination of a detailed reaction mechanism is found to be very difficult, and their characterization at an atomic level is also, although functionalized carbons are found to be very active for several reactions such as oxidation of aromatic compounds, decarboxylation of fatty acids, and selective oxidation dehydrogenation of hydrocarbons [24]. Here we emphasize graphene and graphene oxide-based materials.

Oxidation Reactions

Catalysis by Graphene Oxide and Graphite Oxide

Dreyer and Bielawski [25] explained that synthesized graphene oxide and graphite oxide, which is exfoliated version of graphite oxide give a highly disrupted graphene network. GO has a huge application in catalysis like easy synthesis procedures, low cost, it can be easily recovered by filtration, and it also has a surface to volume ratio. As it is already mentioned that the edges and basal plane of GO contain numerous oxygen functional groups like carbonyl, epoxy, carboxylic acids, and hydroxyl, all these groups are responsible for the acidic character, chemical activity, oxidative nature, and catalytic activity of GO.

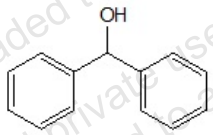


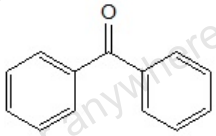
However, GO can be used as a catalyst in numerous reactions. Bielawski and his coworkers [26] reported the effect of GO on the oxidation of alkenes to diketones, alcohols to aldehyde and diketones, and oxidation of alkynes to hydrates at 75-150 °C in air. Above oxidation reactions are highly selective. For example, the yield in the oxidation of cis1,2-diphenylmethane-1,2-diol to 1,2-diphenylethan--1,2dione was 96%, and 98% for diphenylmethanol to benzophenone. Interestingly, whereas GO oxidized 1,2diphenylethene to 1,2-diphenylethane-1-2-dione with 56% conversion, it was either inactive or could only catalyze the isomerization of other alkene systems.

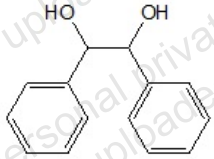
So, it is found that cis-1,2-diphenylethene is reactive because of a combination of cis geometry and aromatic substituents. To determine the catalytic activity of GO researchers performed several experiments inert nitrogen environment and found that absence of oxygen results in very little oxidation, and also GO can be extracted from the reaction mixture and reused up to several cycles. But, GO catalyst has very low activity and to obtain a reasonable yield in 24 h high carbon to substrate ratio up to 200% is required. Although GO catalyst requires high loading and has low activity, it has the main advantage that it has a high turnover frequency per dollar as compared to tetrapropyl ammonium per ruthenate oxidation catalyst.

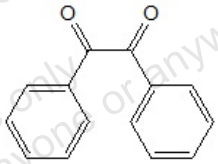
GO was found to catalyze other reactions, such as oxidation of sulfides to sulfoxides and the coupling of thiols to disulfides [27], dehydrogenation of various hydrocarbons and oxidation of methylbenzenes to their respective aldehydes, diarylmethanes to their respective ketones, and other hydrocarbons with sp3-hybridized C–H bonds [28]. It has also shown high activities for the Claisen–Schmidt coupling reactions [29], Friedel-Crafts reactions [30], Aza-Michael additions [31], and ring-opening polymerization [32].

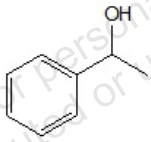
Oxidation of Various Alcohols

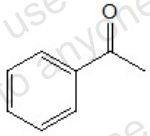


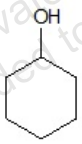


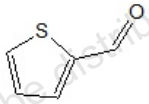


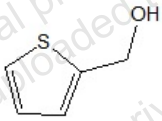












In the initial experiment, under ambient conditions and in the presence of 20 wt% of GO, benzyl alcohol ($PhCH_2OH$) is heated at 100 °C for 14 h (Scheme **1**). After that, it is filtered several times and gives the mixture of benzaldehyde ($PhCHO$)/$PhCH_2OH$ in the molar ratio of 1:3, as verified by 1H NMR spectroscopy. Under these conditions, the formation of any other by-products and benzoic acid ($PhCO_2H$) were not observed.

Scheme 1. Oxidation of benzyl alcohol using graphene oxide (GO).

The reactivity of the above carbocatalyst is studied by using various primary and secondary aliphatic and benzylic alcohols under ambient conditions such as 100°C, 24 h and 200 wt% GO, which results in the highest conversion of $PhCH_2OH$ into its oxidized products. Table **1**, entries 1–3 reveals that benzylic alcohols have moderate to high product conversion efficiency. Table **1**, entry 4 reveals the high catalytic power of GO to oxidize cyclohexanol. Table **1**, entry 5 explains the conversion of 2-thiophenemethanol into aldehyde, and the sulfur oxidation does not take place. The latter results explain that GO exhibit broad chemoselectivity and have a high tolerance towards functional groups, so GO can be used to overcome the challenges given by transition metal catalysts.

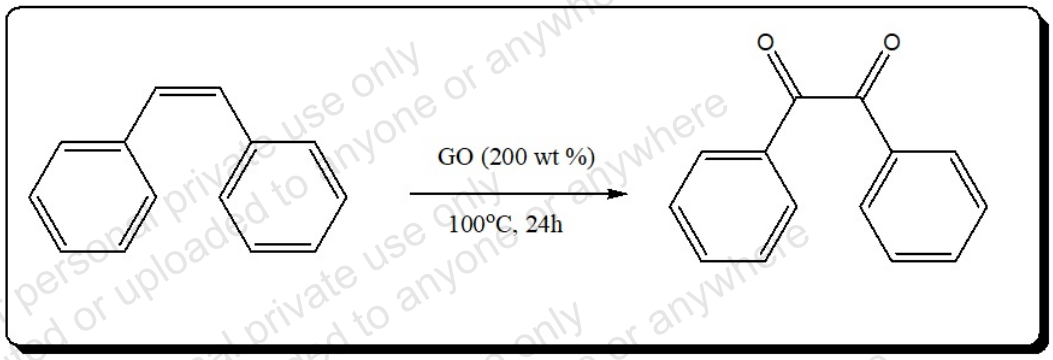


Table 1. Oxidation of Various Alcohols Using GO[a].

Entry	Alcohol	Product	Conversion (%)
1[b]			> 98
2[b]			96
3[d]			26
4			> 98
5[d]			18

Oxidation of Cis-Stilbene

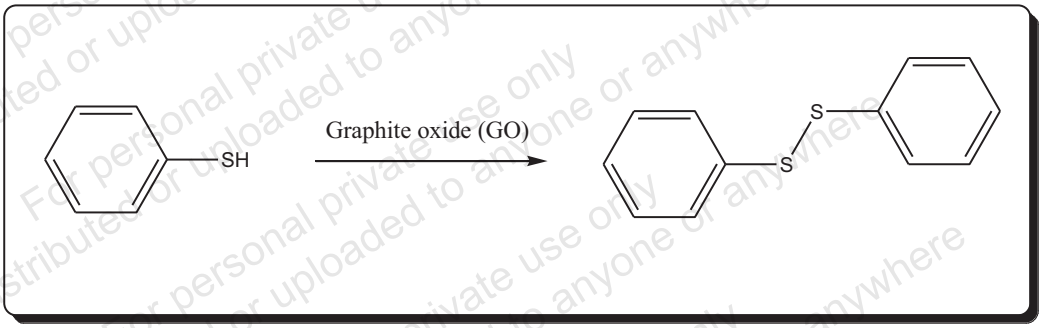
As mentioned above, GO can undergo the oxidation of various alcohols, so nowadays various efforts are used to explore the ability of GO to catalyze the oxidation of unsaturated hydrocarbons. As illustrated in Scheme **2**, under the optimized conditions on treatment of cis-stilbene at 100°C for 24 hours 49% benzil is isolated (56% conversion by NMR spectroscopy); in the crude reaction mixture, benzene or any oxidation product is not found.

For personal private use only Not be distributed or uploaded to anyone or anywhere

Scheme 2. Oxidation of cis-stilbene using GO.

To facilitate the oxidation process, it is necessary to combine cis geometry with aromatic substituents because when other alkenes (trans-stilbene, 3-hexene, cyclohexene, and b-methyl styrene) are used as substrates under the same environment, no reaction or isomerization is observed these may be due to orientation of the interaction tangled between catalyst surface and olefins or may be due to steric hindrance.

Oxidation of Organosulfur Compounds



The oxidation of sulfides and thiols resulted in various applications in drug metabolism, synthesis, and preparation of bioconjugates. Several methods have been investigated for the oxidation of organosulfur compounds but all the methods are associated with a major drawback of over-oxidation. For example, dimerization of thiols resulted in thiols and then it further undergoes the oxidation of disulfinates, thiosulfinates, disulfones, and sulfinylsulfones. Similarly, the oxidation of sulfides resulted in sulfoxides along with sulfones and sulfonic acid.

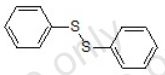
To solve this problem of overoxidation several advanced catalysts such as transition metal with active species are investigated. Among all the metals, catalyst based on palladium, iron, and molybdenum decreases the reaction time and increases the selectivity for the desired product. Despite this advantage, because of toxicity and separation issues, numerous metal catalysts cannot be used in biotechnological and pharmaceutical applications.

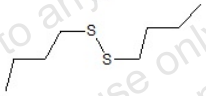
So for the organosulfur compounds, it is necessary to develop highly active metal-free oxidants. Furthermore, the heterogeneous catalysts allow not only the easy and facile separation of the target compounds by distillation and filtration but also reuse and recovery of the catalyst itself. We found that many of the above-mentioned challenges to ing organosulfur oxidants can be solved using a graphene oxide catalyst.

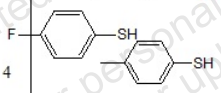
Oxidation of Thiols

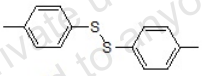
In an initial experiment, 25 mg of thiophenol is reacted with 75 mg of GO by using 0.3 ml of $CHCl_3$ at 100 °C for 10 min in a closed vessel (Scheme **3**). After that, the above reaction mixture is dissolved in 50 ml of $CHCl_3$ and then it undergoes filtration to remove the volatile solvent, the thiol is determined by 1H NMR spectroscopy ($CDCl_3$) to convert them into diphenyl disulfide.

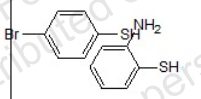
Scheme 3. Oxidation of thiol using graphene oxide (GO).

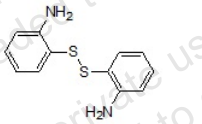


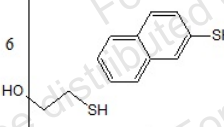


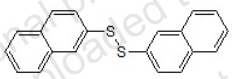


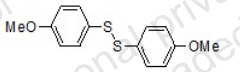


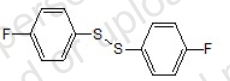


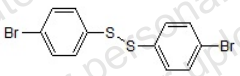


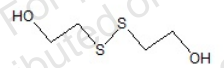












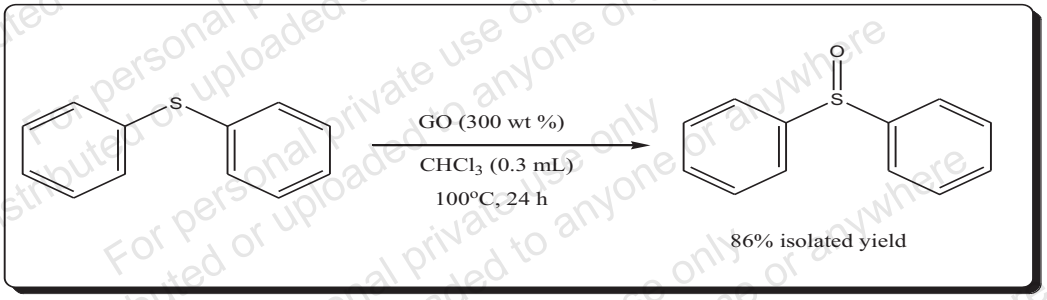
By using the above-mentioned experimental conditions (25 mg thiol, 15 mg GO, 0.3 mL $CHCl_3$, 100°C, 10 min), after that, we determined the substrate scope of this method. As presented in Table **2**, the reaction of various thiols with GO resulted in exceptional conversion to their disulfides, and by dissolving the reaction mixture in 50 ml $CHCl_3$, filtering the remaining carbon, removing the volatile solvent under close atmosphere, in some cases purification by using column chromatography resulted in the pure products.

Entries 1, 4–9 of Table **2** show that the aryl thiols have a longer reaction time of 30 min as compared to alkyl thiols which are 10 min (entries 2–3, 10), but the reactivity of aryl thiol is higher than alkyl thiol these is because of higher activity of GO towards arene functionalized substrate. To further indicate the superior reactivity of aryl thiol over alkyl thiols, 25 mg of thiophenol and 1-butanethiol in 1:l molar ratio is reacted with 60 wt% of GO at 100°C for 10 min. The 1HNMR spectroscopy revealed the 63% conversion of reactant into product and the product mixture contains a 1.0:5.0:2.9 molar ratio of dibutyl disulfide: butyl phenyl disulfide: diphenyl disulfide along with 34% unreacted 1-butylsulfide and a <5% unreacted thiophenol.

The incorporation of electron-donating or withdrawing substituents to the aromatic thiols does not influence the quantity of desired product. For example, electron-rich diols as given in entries 4–7 and electron deficient thiols as presented in entries 8–9 of Table **2** gives the exceptional 94-99% yield of their

respective disulfides, in all the above reaction, no over-oxidation and nitrogen oxidation in case of 2-amino thiophenol is detected, which has been occurred by use of chromic potassium sulfate ($CrK(SO_2)_2.12H_2O$) and other transition metal-based oxidation catalysts [33]. Although these challenges are overcome by the use of more advanced metal species such as cobalt porphyrins and imidazole [34], MOFs, and various bismuth species [35] but these catalysts do not show the extent of reactivity as shown by GO.

Table 2. Oxidation of various thiols using GO[a].



Entry	Starting material	Product	Reaction Time	Yield[b] (%)
1			10 min	100
2			30 min[c]	77
3			30 min[c]	90
4			10 min	95
5			10 min	96
6			10 min	97
7			10 min	97
8			10 min	99
9			10 min	94
10			30 min[c]	75

[a]All reactions were performed at 100°C in sealed 7.5 mL vials using 25 mg thiol, 15 mg GO (60 wt%) and 0.3 mL $CHCl_3$ for the indicated reaction time. [b]Isolated yield after purification by column chromatography. [c]Relatively low yields (40–65%) were observed after 10 min; higher yields were obtained after 30 min.

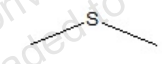
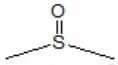
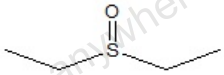
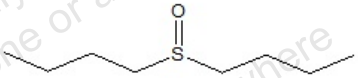
Oxidation of Sulfides

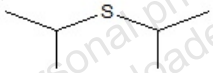
In an initial experiment, diphenyl sulfide is oxidized to diphenyl sulfoxide at 100°C (300 wt% GO) after 24 h 86% isolated yield was obtained (Scheme **4**), and in the reaction mixture, no other oxidation product is observed. In the way illustrated above, the reaction is improved concerning reaction time, reaction temperature, and GO loading. It is found that GO concentration below 300 wt% does not give the desired product, yet with an increase in GO loading, no enhancement in isolated yield is observed.

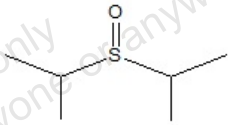


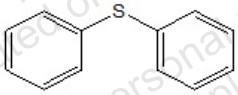


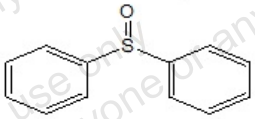


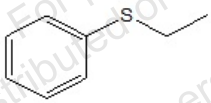


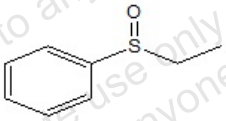


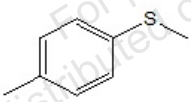


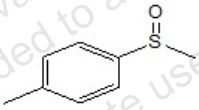


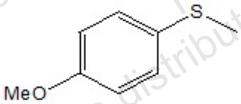


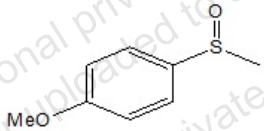


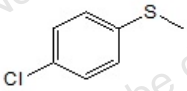


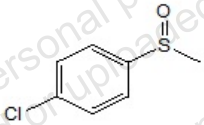












Scheme 4. Oxidation of diphenyl sulfide using GO.

Here the GO loadings required are much higher than that of metal catalysts but their heterogeneity and low cost make them more feasible to use. It is found that the used GO loadings which undergo the partial deoxygenation as given below, can be again reoxidized to GO by using the oxidation method, which was used by the graphite starting material. The above mention thiol coupling shows that when carbons other than GO are used, such as activated carbon, graphite, and hydrazine-reduced graphene oxide minimum reactivity is observed.

As shown in Table **3**, by using the optimum conditions like 75 mg GO, 25 mg sulfide, 0.3 mL $CHCl_3$, 24 h, and 100°C a large number of sulfides can be converted into their respective sulfoxides. In most cases, after purification by column chromatography exceptional yields of their subsequent products are gained. Differences in the electronic structure of the arene substituted sulfides slightly affect sulfoxide product yield. For example, an electron-rich sulfide (*p*-methoxythianisole, entry8) on oxidation gives a 96% product yield, while an electron deficient sulfides (*p*-chlorothianisole, entry 9) gives the 81% product yield. As Compared to Ru and Fe catalysts (using H_2O_2 or O_2 as the oxidant), GO resulted in an increase in selectivity and product yield for the sulfoxide over the sulfone.

Table 3. Oxidation of Various Sulfdies by Using GO[a].

Entry	Starting material	Product	Yield[b]
1			89%
2			92%
3			90%
4			51%
5			86%
6			85%
7			75%
8			96%
9			81%

[a]All reactions were performed at 100°C in sealed 7.5 mL vials using 25 mg sulfide, 75 mg GO (300 wt%), and 0.3 mL $CHCl_3$ for 24 h. [b]Isolated yield after purification by column chromatography.

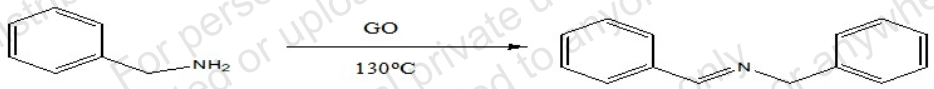
Oxidation of Amines

A large number of efficient methods have been for the oxidation of alcohols into their respective carbonyl groups but the methods for the catalytic oxidation of amines into imines are still not much studied, although imines are a good source of nitrogen in many chemical reactions [36 - 40]. In the conventional method, imine is prepared by condensation of primary amines and aldehyde and ketones [41], but this method requires some critical conditions like longer reaction time and catalyst Lewis as the catalyst [42]. In the last few years, to optimize these reaction conditions, many methods have been developed such as self-condensation of primary amines, oxidation of secondary amines, and direct coupling of amines and alcohols [43 - 47].

In recent years, a large number of catalysts have been explored for the oxidation of amines [48, 49]. But these catalysts still have some drawbacks, such as high toxicity, high cost, difficult preparation methods, and critical reaction conditions. Therefore, a catalyst with high selectivity, separability, and easy preparation procedure is required.

Recently, Go has drawn widespread attention [50 - 52]. Go along with its derivatives are widely used as a metal-free catalyst [53 - 58]. Because of the presence of a large number of oxygenated functional groups in GO, GO has high catalytic and oxidation capabilities [59]. Several advantages of GO like low toxicity, simple preparation method, and tendency to get separate makes it a good catalyst for oxidation of amine.



It is found that GO is an efficient catalyst for the oxidation of amines into imines but the effect of various functional groups on Go and their decreased activity in recycling experiments are not clarified [60]. Bermudez and co-workers [61] reported the use of hydrogen peroxide (H_2O_2) as the oxidant in GO-catalyzed oxidation of amines and disclose the effect of GO and H_2O_2 and GO on the selectivity of products.

But, in several reactions, the effect of free radical is uncertain so because of the above reason the mechanism of oxidation of amines catalyzed by carbocatalysts, which is necessary for efficiency and design of catalyst, is still in doubt. It is observed that GO and its derivative such as improved graphene oxide (IGO), can oxidize the amines into their respective imines in the absence of oxygen and catalyst and improved graphene oxide has higher reactivity for amine oxidation. GO can function as both catalyst and oxidant, the epoxy and hydroxyl groups present in GO act as an oxidant, and Carboxyl groups along with defects and edges play the role of catalyst.

This remarkable metal-free reactivity of graphene oxide has encouraged researchers to explore the probabilities offered for catalytic oxidation of amines into imines. Go is reported as an easily available, easily applicable, cheap, recyclable, and efficient catalyst for the direct conversion of amines into imines. It is the first suitable metal-free catalytic method that is used for the synthesis of imine from various amines by using molecular oxygen as the oxidant under neat conditions [62].

Benzylamine acts as an intermediate for several polymers, pharmaceuticals, and dyes, and it is also used to study the use of graphene oxide in the oxidative coupling reaction of amines. Entry 1 of Table **4** shows that the reaction of GO and benzylamine with p-xylene at 130°C in the air for 8 h resulted in 87.39% of N-benzylidene benzylamine product. Entry 2 of Table **4** shows that when a similar experiment is performed in the absence of GO, only 9.33% of product yield is obtained, which indicates that GO can catalyze the aerobic oxidation of benzylamine.

Table 4. Oxidation of Benzylamine to N-Benzylidene Benzylamine under various conditions[a].

Entry	Condition	oxidant	yield (%)[b]
1	air	GO	87.39
2	air		9.33
3	air	IGO	99
4	argon	GO	46.32
5	argon		<5
6	argon	IGO	66.25

[a]Reaction conditions: benzylamine (2.5 mmol), GO (26 mg), and p xylene (5 mL) at 130°C for 8 h, entry 1−3 in air condition, entry 4− 6 in argon condition. [b]Isolated yield.

Entry 4 of Table **4** states that when the above reaction is carried out in the same condition in the presence of argon results in 46.32% of product yield. Entry 5 of Table **4** shows when the above reaction is carried out with argon in the absence of GO then less than 5% of the product is obtained which indicates that GO also plays the role of oxidant in this reaction.

Nitrogen-Doped Graphene Catalysts

Nowadays, N-doped graphene has become brilliant catalysts for oxygen reduction reaction (ORR) battery and fuel cell applications. The inclusion of nitrogen atom

changes the charge distribution of surrounding carbon, and spin density and broadens the bandgap of GO. Generally, the nitrogen can be incorporated into carbon lattice in three forms: pyridinic N, quaternary (graphitic) N and pyrrolic N. Since all the three forms of nitrogen affect the oxygen reduction reaction and the improvement in the reactivity is depends on the amount of quaternary and pyridinic nitrogen. Despite the above advantage use of N-doped graphene in various reactions is not much studied only a few studies like oxidation of benzene into phenol [63] and of a range of benzylic alcohols [64] are available. N-doped graphene is synthesized by flowing NH_3 over GO and it is found that the quaternary nitrogen increases the catalytic activity of oxidation of benzylic alcohol into their respective aldehyde. The incorporation of quaternary nitrogen into GO can be increased by increasing the temperature up to 900°C.

Oxidation of Alkyl Arenes and Alcohols

In organic synthesis, the selective oxidation of organic compounds at laboratory and industrial scales is a major challenge. In the aerobic oxidation reaction, there are generally three major considerable aspects are eradicating the requirement of the activators like inorganic bases and accomplishment of the reaction without activation in a green solvent at room temperature.

At an industrial scale, the grouping of these characteristics is highly challenging and this grouping provides benefits for chemical reactions. To solve the above challenge catalyst is the key, several studies are ongoing to get a suitable catalyst having all aforementioned aspects. Recently the researcher emphasis on the development of the catalyst by using the green and biometric principal. Because of this reason metal phthalocyanines and metal porphyrins are used as biomimetic catalysts in various oxidation reactions.

Zhang *et al*. [65] reported that the oxidation of alcohols and alkyl arenes in the solvent-free aerobic atmosphere with Pd@ N-doped carbon at 120°C resulted in very low product yield and the use of Pd in the catalyst as an active site also restrict its application. The aforementioned drawbacks lead to the development of new catalysts such as copper(II) tetrasulfo phthalocyanine reinforced on three-dimensional nitrogen-doped graphene-based frameworks (CuTSPc@3D-(N)GFs). The above catalyst is the first catalyst that was synthesized by using 3D-(N)GF--supported phthalocyanine and it has the unique property of selective aerobic oxidation of alcohols and alkyl arenes into their respective carbonyl groups. The selective aerobic oxidation reactions are conducted at room temperature in an ecofriendly environment for a short reaction time and resulted in excellent product yield.

To optimize the required amount of solvent and catalyst, the oxidation of 2,3-dihydro-1H-indene is carried out by using 0.4 mol% of H_2O and Cu as a solvent for both the reactions at room temperature and the results are given in Table **5**. The important advantage of 3D-(N)GFs support are: (i) They have high surface area, macroporous structures, good physical and chemical stability (ii) simple preparation method, (iii) the presence of a bifunctional heterogeneous catalyst (copper(II) as the active site and N as the base) eliminates the requirement of activators like inorganic bases, (iv) chemical modification of the surface with nitrogen doping increases the reactivity and in catalytic oxidation, they also improves the oxygen interaction with substrate and, and (v) because of its hydrophilic nature it is easily soluble in water which is used as a reaction solvent.

Entries 2-4 of Table **5** present the catalytic oxidation of benzaldehyde and 2,3-dihydro-1H-indene using GO, 3D-(N)GFs, and CuTSPc [66]. Entry 2 of Table **5** shows that when GO (0.005 g) is used as a catalyst under a mild condition in oxidation reaction results in a very low product yield.

Table 5. Comparison of the Results Obtained From Cutspc@3D-(N)Gfs with GO, Cutspc, and 3D-(N)Gfs for the Oxidation Reactions.

Entry	Catalyst	Product	Yield[b] (%)	Selectivity[b] (%)
1	CuTSPc@3D-(N)GFs	2,3-Dihydro-1*H*-indene	98	> 99
		Benzaldehyde	98	> 99
2	GO	2,3-Dihydro-1*H*-indene	24	> 99
		Benzaldehyde	30	> 99
3	3D-(N)GFs	2,3-Dihydro-1*H*-indene	33	> 99
		Benzaldehyde	35	> 99
4	CuTSPc	2,3-Dihydro-1*H*-indene	86	97
		Benzaldehyde	88	98
5	CuTSPc@MCM-41	2,3-Dihydro-1*H*-indene	75	98
		Benzaldehyde	81	99

[a]**Reaction conditions: 2,3-dihydro-1H-indene or benzyl alcohol (1.0 mmol), catalyst, H2O (4.0 mL), air (1 atm), r.t., 3 h.** [b]**Yield and selectivity determined by GC analysis.**

It is found that the use of 3D-(N)GFs support increases the adsorption of aromatic reactants these may be due to the p-p interaction between graphene and benzene skeleton of reactant. Furthermore, the interaction of 3D-(N)GFs with nitrogen-doped support resulted in the adsorption of oxygen on the bridge sites of graphene by using migration energy of more than 1.0 eV. Graphene contains mobile

oxygen, which endorses hydrogen elimination resulting in the enhancement of the aerobic oxidation of organic compounds. Entries 1 and 4 of Table **5** show the increase in the product yield as compared to the homogenous catalyst, several factors improve the yield, such as the presence of basic sites on solid and p-p interaction between support and aromatic groups favor the proximity of reagents with the catalytic site.

Selective Oxidation of Olefins and Alcohols

Although the selective oxidation of alcohols and olefins with molecular oxygen is very much important for the environment, life, and synthetic chemistry, it is still a very difficult task. Several reagents and methods have been discovered to accomplish these oxidation reactions. Most of the oxidation reaction uses the fixed amounts of heavy metal ions such as Mn, Cr, Co, and Fe and explosive oxidants such as hydrogen peroxide and peroxy acids. Because of environmental issues, there is a need to develop a safer and cheaper heterogeneous catalyst for oxidation. A large number of noble metal nanoparticles like Pd, Ru, Pt, and Au have been studied for use in the oxidation of alcohols and olefins.

Graphene has several advantages, such as it has a high surface area which helps in the transfer of reactant and product by scattering the metal nanoparticles micropore-free structure with one or a few sheet layers, it also has appropriate electrical conductivity, which helps in the transfer of electrons during catalysis process, and also have high chemical reactivity, and it is also found that the graphene has p character which is responsible for interaction between aromatic derivatives and graphene and this interaction makes the reactants available for active sites. Because of the large availability and low cost of graphite, it can be easily broken down into individual graphene by using chemical and physical methods. Traditionally it can be broken down into graphene using several methods such as liquid-phase exfoliation, use of graphite intercalation compound, oxidation exfoliation, and electrochemical exfoliation. In the last few years, it has become a great challenge to modify graphene's mechanical, chemical, and electronic properties by doping using N, B, and P elements.

It is found that N-dopants can decline the formation of “re-graphitized” carbon regions in the carbon skeleton and also, they are favorable sites to enhance the nucleation of particle and decreases particle size. be usually observed as favorable anchor sites or defects for enhancing particle nucleation and reducing the particle size. N dopants have several advantages, such as they can change the electronic structure of the carbon matrix, improve the interaction between the guest molecule and carbon, and also be responsible for the giving metal like d-band to carbon which hosts the reactive species. The effective heterogeneous oxidation

reaction of both alcohol and olefins is carried out by using molecular oxygen over a Co_3O_4/N-doped graphene hybrid (Co_3O_4/RGO-N) catalyst. It is observed that the dispersed Co_3O_4 NPs and well-exfoliated N-doped graphene can be grown simultaneously by employing a one-pot hydrothermal reaction using NH_3 solution. Here we discuss the structural characteristics of Co_3O_4/RGO-N and its performance in the green oxidation of olefins and alcohols [67].

Co_3O_4/RGO-N hybrid is used in the epoxidation of styrene. Entries 1 and 2 of Table **6** reveal that amides like DMF and DMA can be used to get the high conversion of styrene up to 97.7 and 86.2% and high epoxide selectivity of 72.7 and 63.8%. along with the desired product small amount of cleavage product like benzaldehyde is also observed.

Table 6. Epoxidation of Styrene by O_2 in Different Solvents Over Co_3O_4/RGO-N[a] in different solvents over.

Entry	Solvent	Conversion (%)	Epoxide selectivity (%)
1	DMF	97.7	72.7
2	DMA	86.2	63.8
3	Dioxane	77.7	55.7
4	DMSO	26.3	15.2
5	Toluene	0	0
6	n-Heptane	0	0
7	1-Butanol	0	0
8[b]	DMF	22.8	49.1
9[c]	DMF	79.9	66.0
10[d]	DMF	98.7	69.9

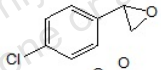
[a]Reaction conditions: temperature (100◦C), reaction time (3 h), Co_3O_4/ RGO-N (20 mg), styrene (8 mmol), DMF (25 mL), low rate of O_2 (20 mL min-1). [b]The reaction was carried out at 80◦C. [c]The reaction was carried out at 90◦C. dThe reaction was carried out at 110◦C.

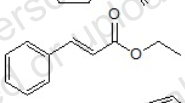
Entries 3 and 4 of Table **6** show that by using DMSO and dioxane solvent certain amount of styrene conversion is obtained but their epoxide selectivity is very low. Entries 5-7 of Table **6** reveals that by using toluene, n-heptane, or 1-butanol

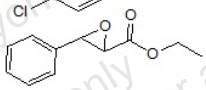
solvent, no products are obtained. Entries 8-10 of Table **6** present the temperature dependency of oxidation reaction and we found that at the temperature 80 -90°C both conversion and selectivity decrease and a small decrease in selectivity is observed at higher temperature (110°C).

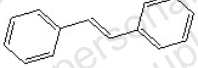
Entry 2 of Table **7** shows that Co_3O_4/ RGO gives the relatively low activity (57.3%) and lower epoxide selectivity (70.3%) as compared to Co_3O_4/ RGO-N. Entry 3 of Table **7** shows that Co_3O_4 seems to be poorer in catalyzing the epoxidation of styrene. Entry 4 shows that significant catalytic activity can be observed over pure RGO-N alone. Entries 5-7 reveal that the use of commonly used oxidation catalysts such as MnO_2, Fe_3O_4, and CuO results in low activity and low epoxide selectivity. The above results show that separated Co_3O_4or RGO-N gives the lower catalytic activity while hybrids result in the superior catalytic activity suggests that Co_3O_4 and N-doped graphene play synergistic roles in the Co_3O_4/RGO-N hybrid for the selective epoxidation of styrene.

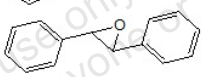
Table 7. Catalyst Screening in the Epoxidation of Styrene by O_2[a].

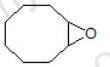


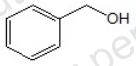


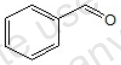


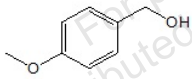


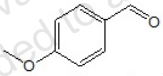


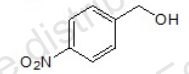


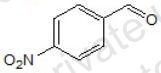


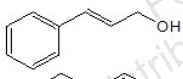


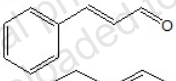


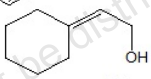


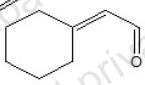


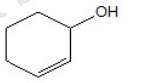


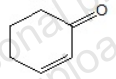


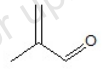












Entry	Catalyst	Conversion (%)	Epoxide selectivity (%)
1	Co_3O_4/RGO–N	97.7	72.7
2	Co_3O_4/RGO	57.3	70.9
3	Co_3O_4	38.6	67.6
4[b]	RGO–N	7.2	58.3
5	MnO_2	5.2	57.7
6	Fe_3O_4	32.2	63.4
7	CuO	3.5	42.9

[a]**Reaction conditions: temperature (100°C), reaction time (3 h), the amount of M (0.15 mmol), styrene (8 mmol), DMF (25 mL), low rate of O_2 (20 mL min-1).** [b]**Reaction conditions: 7.8 mg RGO-N was added.**

The flexibility of the Co_3O_4/RGO-N catalyst is further explained by using different types of olefins used as substrates under optimized conditions (Table **8**). Entry 2 reveals that using styrene with an electron-donating group such as 4-methylphenylene results in a similar conversion to styrene (entry 1), but it has

high epoxide selectivity of 80.6%. Entry 3 shows that the presence of electron-withdrawing group on styrene results in lower conversion and lower epoxide selectivity of 70.7% as compared to unsubstituted styrene. Entry 4 shows that the use of ethyl cinnamate results gives a lower conversion of 55.6% but gives a high epoxide selectivity of 83.9%.

Table 8. Selective Oxidation of Alkenes and Alcohols Over the Co3O4/RGO-N Catalyst[a].

Entry	Substrates	T (h)	Conversion (%)	Product	Selectivity (%)
1[b]		3	97.7		72.7
2		3	97.5		80.6
3		4	96.5		70.7
4		30	55.6		83.9
5		10	95.9		98.3
6[c]		2	>99.9		94.9
7[c]		7	93.9		>99.9
8[c]		2	98.1		>99.9
9[c]		2	99.8		>99.9
10		2.5	>99.9		94.4
11[c]		1	92.5		91.5
12[c]		2	98.2		>99.9
13[c]		2	95.4		>99.9

[a]Reaction conditions: substrate (1.5 mmol), Co3O4/RGO-N (20 mg), DMF (25 mL), temperature (100◦C), low rate of O_2 (20 mL min-1). [b]8 mmol of the substrate was added. ‘sup> The reaction was carried out at 120◦C.

Entries 5 and 6 revels that by using trans-stilbene and cyclooctene higher selectivity (98.3% and 94.9%) and conversion (95.9% and >99.9%) is obtained.

Entries 7-9 show that the use of both electron-donating and electron-withdrawing substituents results in high conversion (>93%) and high selectivity (>99%). Entries 10-13 show that oxidation of allylic alcohols or other aliphatic unsaturated alcohols results in the respective unsaturated aldehydes/ketones without significant oxidation of the double bond.

REDUCTION REACTIONS

Reduction of Nitro Compounds

Nitro compounds such as 4-nitrophenol (4-NP) and 2-nitrophenol (2-NP) are highly soluble in water and are responsible for water pollution and they are referred to as priority pollutants. To date, several methods have been used to convert nitro pollutants into amines [68 - 72]. To remove the water pollutants generally used, three methods are photocatalytic degradation, catalytic reduction, and adsorption [73].

The catalytic reduction method is used to convert toxic nitrophenols into their corresponding amino phenols. The reduction process is an important method to remove toxic pollutants such as nitroarenes and convert them into amino arenes. The amino arenes play an important role in the synthesis of dyes, pesticides, pharmaceuticals, and have several advantages in the chemical industries [74 - 79]. Catalytic reduction is one of the most efficient methods used for the reduction of nitroarenes, by using the heterogenous catalysts the 4NP and 2-NP are converted into 4aminophenol (4-AP) and 2-aminophenol (2- respectively. Because simple processing, high efficiency, and economic nature of heterogenous catalyst make it a suitable reagent for the catalytic reduction of nitroarenes. Subsequently, the appropriate design and careful selection of the heterogeneous (nano) catalysts results in the enhancement of the reduction process.

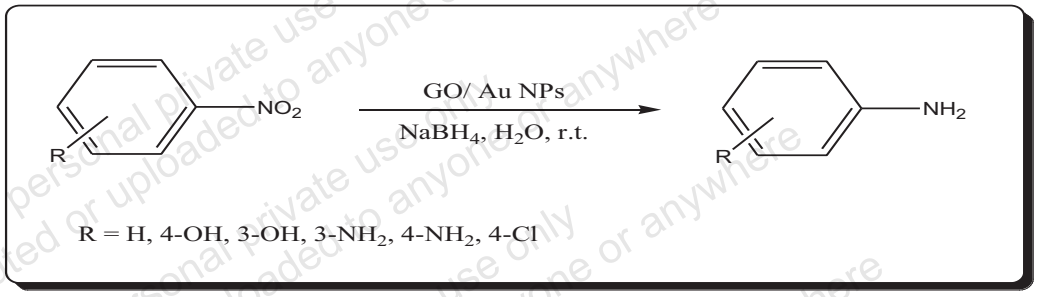
At present several heterogeneous catalytic reduction processes have been discovered which does not use water-soluble toxic solvents [80 - 84]. Because of the presence of sp^2 hybridized carbon atomic layer in graphene, it becomes an appropriate candidate for catalytic reduction of nitroarenes. Geim and colleagues in 2004 reported that by using a peeling method having a scotch tape, single-layer graphene can be prepared [85]. Hexagonal flat layer carbon sheets of graphene have the special properties of material science, physics, mechanics, and chemistry [86 - 90] and it also has several advantages in hydrogen storage, catalysis, field emitters, and hydrogen storage. To prepare the heterogeneous catalyst graphene has a high tendency of immobilization of metal oxide between the layers or on the surface, because of above mention property graphene becomes an excellent (nano) catalyst support.

Graphene has very good conductivity, which is responsible for electron transfer during various transformations. In between the reaction steps, electric polarization is developed between the substrates and graphene, which is responsible for the generation of thermal and electrical conductivity that is useful in various processes [91 - 96]. In recent years several graphene derivatives such as functionalized graphene, reduced graphene oxide, and graphene oxide have gained significant attention [97 - 101]. Considering their excellent properties, graphene-based nanostructures with high catalytic activity are one of the outstanding selections for the synthesis of diverse organic compounds [102, 103]. With regards to the greener aspect of the catalytic (nano) systems, developing the most facile and environmentally benign strategies in the efficient remediation of toxic/hazardous nitroarenes is of specific significance worldwide [104].

Graphene-Based (nano) Catalysts in the Reduction of Nitro Compounds

GO and RGO

In 2012, Chen *et al*. reported that nitrogen-doped graphene (NG) can be used as a catalyst for electrochemical reduction of aromatic nitro compounds such as 2,4dinitrotoluene (2,4-DNT), 1,3-dinitrobenzene (1,3-DNB), 2,4,6-trinitrotoluene (TNT) and 1,3,5-trinitrobenzene (TNB) [105].

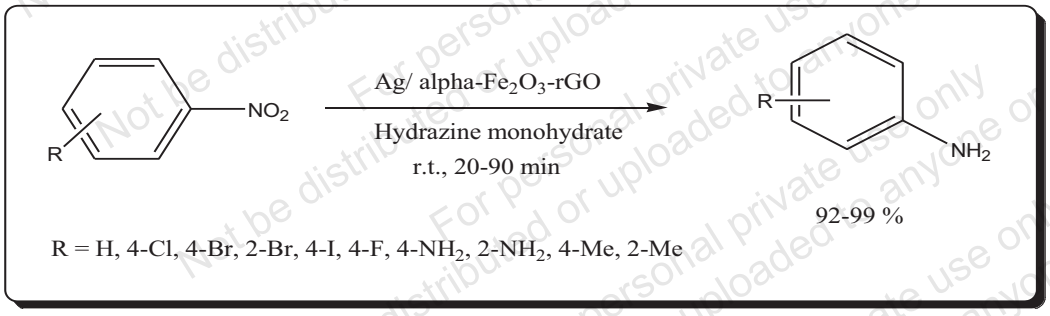


Colunga and his co-workers stated that using biogenic sulfide graphene oxide can undergo the catalytic reduction of various pollutants like 3-chloronitrobenzene (3CNB) and reactive red 2(RR2) [106]. It is found that the use of GO nanocatalyst in the reduction of 3-chloronitrobenzene results in a high product yield. Mahata and his co-workers, by using cashew leaf extract, discovered an economical, efficient, and described an efficient, economical, and green route for the synthesis of graphene oxide [108].

Au/Graphene-Based Nanocomposites

Adhikari and colleagues stated that GO-based supramolecular hydrogels can be prepared by using biologically active polyamines such as tris (aminoethyl) amine, spermine, and spermidine. Moreover, by using vitamin C reductant and greener route they synthesize the Ag, Au, Pt nanoparticles, and RGO-based hybrid hydrogels *via* the reduction of the metal ions and GO The obtained results reveal that metal nanoparticles are uniformly distributed on reduced graphene oxide nanosheet.

Fakhri and colleagues reported an easy and facile route for the synthesis of GO/Au NPs [109]. As shown in Scheme **5** that prepared GO/Au NPs undergo the

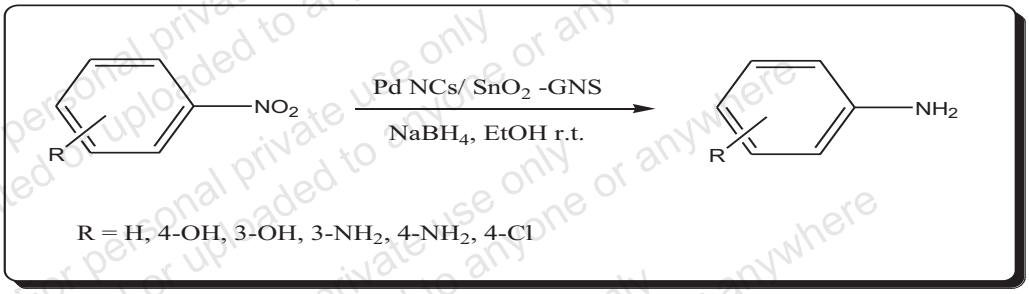


catalytic reduction of nitro compounds at ambient temperature and catalyst can be reused several times.

Scheme 5. Catalytic reduction of the nitroarenes using GO/AuNPs.

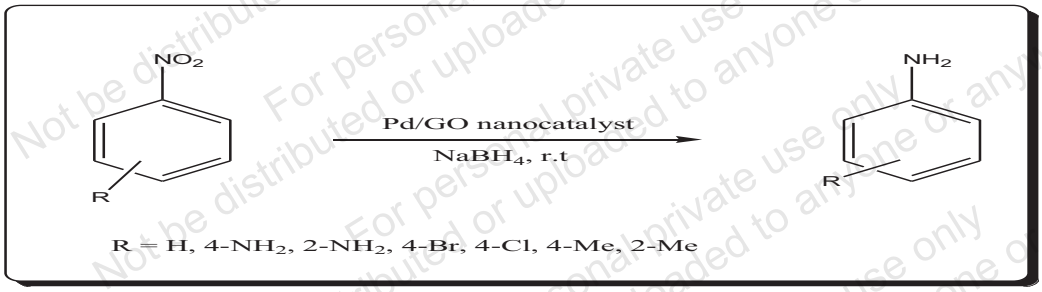
Ag/Graphene-based Nanocomposites

In 2013, Jeon and his co-workers suggested an easy and facile method for the synthesis of Ag nanoparticles decorated on GO surface-functionalized with them mussel inspired dopamine (GO-Dopa) [110]. It is found that the green synthesized Ag/GO- Dopa hybrid by using $NaBH_4$ undergoes the catalytic reduction of 4-NP to 4-AP. Paul and colleagues in 2016 reported a novel method for the hydrothermal synthesis of Ag/ Fe_2O_3 present on rGO surface by using urea as a hydroxylating agent and polyethylene glycol (PEG4000) as a surfactant [111]. As shown in Scheme **6** synthesized Ag/ Fe_2O_3 -rGO nanocomposite undergoes the effective catalytic reduction of nitro compounds into their respective amines and by using an external magnet catalyst can be reused five times.



Scheme 6. Catalytic reduction of nitroarenes using Ag/Fe_2O_3-rGO nanocomposite.

Pd/Graphene-Based Nanocomposites

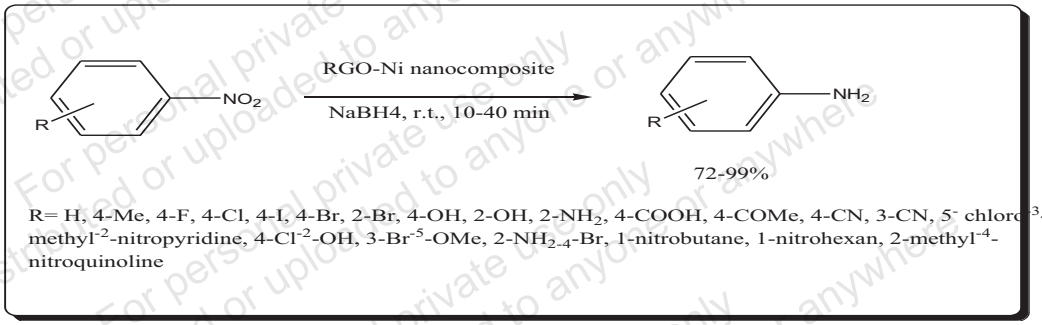


Li and his co-workers developed a synthesis method for the preparation of ultrafine Pd nanocrystals (PdNCs) immobilized on the SnO_2-decorated graphene nanosheets *via* immobilization of Pd NPs with 3.4 nm average size on the PDDA

functionalized SnO_2-GNS (SnO_2-GNS) [112]. As shown in Scheme **7** that by using $NaBH_4$.Pd NPs/ RGO the Pd NCs/ SnO_2 -GNS undergoes the extraordinary reduction of 4-nitrophenols by $NaBH_4$ in an EtOH and H_2O (1:2) mixture and the catalyst can be reused for 5 times.

Scheme 7. The reduction of nitroarenes using Pd NPs/RGO.

Zhang *et al*. in 2014 reported an easy and facile route for the synthesis of Go nanocomposite decorated by Pd nanoparticles [113]. It is evident for Scheme **8** that Pd/GO nanocatalyst gives that exceptional catalytic activity during the reduction of aromatic nitro compounds by using $NaBH_4$. The catalyst can be reused 6 times.



Scheme 8. The catalytic activity of Pd/GO nanocatalyst in nitroarenes reduction by $NaBH_4$.

Ni/Graphene-based Nanocomposites

Kubendhiran *et al*. in 2017 by employing reduction of GO with caffeic acid(CA) and the non-covalent π-π stacking interaction between Ni-TPP and RGO fabricated an RGO/nickel tetraphenyl porphyrin (GRGO/Ni-TPP) nanocomposite modified electrode [114]. The above-prepared nanocomposite GRGO/Ni-TPP is used for the reduction of nitrobenzene and it is found that GRGO/Ni-TPP modified electrode results in high product yield and high selectivity.

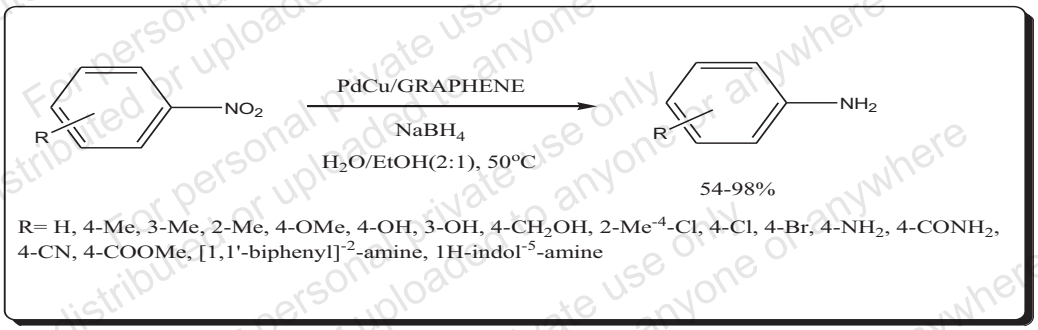
Karthik and his co-workers reported RGO-Ni nanocomposite is synthesized by using L-ascorbic acid as a reducing and capping agent by reduction of GO and $NiCl_2.6H_2O$ under hydrothermal conditions [115]. From Scheme **9** it is concluded that by using $NaBH_4$ the RGO-Ni heterogeneous catalyst results in high catalytic activity during the catalytic reduction of aromatic nitro compounds. By using the magnetic separation method, the above catalyst can be recovered and reused 5 times.

Scheme 9. Catalytic reduction of nitroarenes using RGO-N in a nanocomposite.

Pt/Graphene-based Nanocomposites

Li and his colleagues in 2015 reported a simple method for the fabrication of (Pt NCs/rGO) decorated on rGO by using a water-based, co-chemical reduction process using polyallylamine hydrochloride as a multi-functional agent in the functionalization of GO [116]. It is found that by using $NaBH_4$ the Pt-NCs/rGO composite results in high catalytic activity during the reduction of 4-Nitrophenols and the synthesized catalyst can be used 5 times.

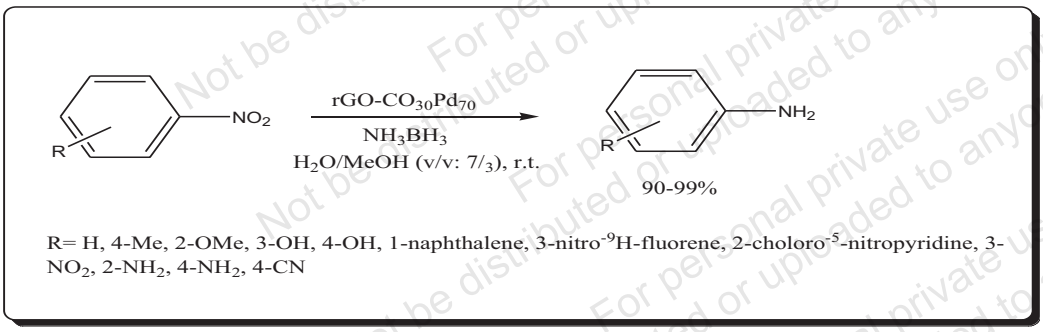
In 2017, Sahoo and his co-workers by using graphene oxide and metal precursor, reported an efficient and green method for the synthesis of d metals (Au, Pd, and Pt)/ 3D-graphene nanocomposites [117]. The metals/3D-graphene nano-composites by using $NaBH_4$ at ambient temperature result in a high catalytic reduction of 4-NP and MB. The catalytic activity rate of metals is as Pt/>Pd/ >Au/3D-graphene for both the pollutants, showing a minimum number of metal nanoparticles results in excellent catalytic activity. The prepared catalyst can be reused 5 times.



Cu/Graphene-based Nanocomposites

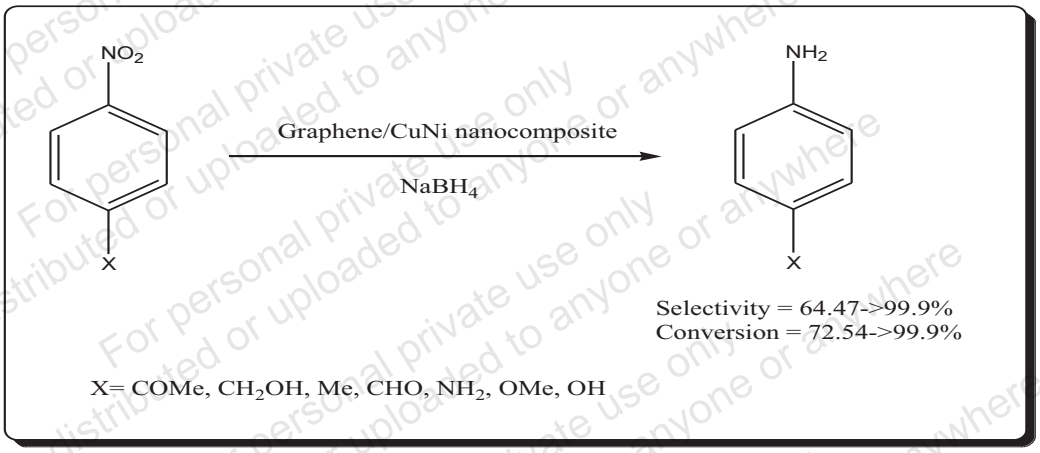
In 2018, Liu and Guo developed a simple approach to fabricate the SH-β--D-RGO/Cu NSs nanocomposite by depositing the Cu nanospheres on thio---cyclodextrin (SH-βCD) functionalized RGO (SH-β-CD-RGO) [118]. The

aforementioned nanocomposite plays an important role in the catalytic reduction of 4-Nitrophenol.



Bimetallic/Graphene-based Nanocomposites

Feng and colleagues fabricated the graphene decorated Pd-Cu NPs by employing co-reduction of $CuCl_2.H_2O$ and $PdCl_2$ [119]. As shown in Scheme **10** that Pd Cu-graphene undergoes the effective nitroarene reduction by using $NaBH_4$ in EtOH: H_2O (1:2) at 50 °C. The obtained results reveal that the Pd Cu-graphene can be reused up to six times.



Scheme 10. Catalytic reduction of nitroarenes using Pd Cu-graphene.

In 2013, Goksu and co-workers reported an efficient method for the fabrication of rGO decorated $Co_{30}Pd_{70}$ alloy (rGO- $Co_{30}Pd_{70}$)NPs by co-reduction of cobalt(II) and Pd(II) acetyl acetates in borane-tertbutyl amine (BTB) and oleyl amine (OAm) mixture [120]. It is clear from Scheme **11** that rGO- $Co_{30}Pd_{70}$ catalyst by using ammonia borane in H_2O/methanol mixture undergoes the catalytic reduction of aromatic nitro compounds into their respective amines and results in good product yield.

Scheme 11. Catalytic reduction of nitroarenes using rGO-Co30Pd70.

Fang and his coworkers developed an easy and eco-friendly method for the synthesis of graphene/CuNi nanocomposite. They synthesized the two-dimensional graphene decorated Cu Ni with 2D nanoparticles of particle size 2 nm. From Scheme **12** it is clear that the graphene/CuNi nanocomposite undergoes the selective catalytic reduction of aromatic nitro compounds by using $NaBH_4$ and the catalyst can be reused up to 25 times.

Scheme 12. Reduction of nitroarenes by graphene/CuNi nanocomposite.

CONCLUDING REMARKS

The previous studies reveal that the metal-free GO has many catalytic applications. The surface area of GO is high, the adsorption capacity of GO towards hydrocarbons, gases, and ions is very high, and also the reaction of GO with oxygenating functionalities resulted in various paths for the introduction and modification of various functional groups.

Although lots of studies are done on the numerous catalytic application of GO, still there are lots of challenges that should be examined and resolved. Among them, the three main important challenges are: (1) As we know that the performance of the GO catalytic system is mainly dependent on composition and structure, so there is a need to develop such methods which undergo the precise characterization for the identification of active sites. (2) Much care should be taken to eliminate the probability that the catalytic activity could be recognized to metal contaminants, even at a trace level. (3) Further understanding and more research are needed to describe the potential cooperative effect of Go on the catalytic activity. To design the balanced metal-free catalyst systems it is necessary to understand the advantages of graphene oxide over the activated carbon and traditional metal oxide. However, the metal-free carbon catalyst has

the above drawbacks. It can be used to solve the various industrial problems related to the traditional catalysts. Since graphene oxide catalysts are synthesized environmentally friendly material, their applications should be explored in green synthesis.

Abstract: Enzymes have catalytic properties and can be used for different purposes as biocatalysts in some industrial processes. However, their applications are limited due to some drawbacks, such as lack of long-term stability and recovery under conditions of any particular process. Enzymes can improve their catalytic activity, stability, reusability, and half life, if these are immobilized on some support. Graphene and graphene based nanomaterials are good supports for enzymes as they are also non-toxic materials in nature. Such materials can also find applications in the fields of medical diagnostics, biofuel cells, biosensors, *etc*. These particular aspects have been discussed in this chapter.

Keywords: Biocatalyst, Biofuel Cell, Biosensors, Graphene, Graphene Oxide, Immobilization, Reduced Graphene Oxide.

INTRODUCTION

Nowadays, graphene and its derivatives are attracting the attention of scientists all over the globe due to their unique properties such as chemical, optical, mechanical, electrical, *etc*. There could be multivalent functionalized and surface loaded efficiently with the number of biomolecules. Apart from it, abundance, easy synthesis, excellent solubility and processability, high surface area, conductivity, and biocompatibility are the added advantages of graphene-derivatives over other carbon-based materials like diamond, carbon nanotubes, fullerene, *etc*. Recent advancement in the synthesis and surface functionalization of this graphene or graphene-based nanostructured materials have opened up new horizons as a host material for polymers grafting and the designing of state-of-the-art nano-biocatalytic systems. Graphene-immobilized nanocatalyst varies from

conventional nano-bioconjugates with respect to functional stability, catalytic efficacy, and applicability. Graphene-assisted biocatalysts find numerous applications in various fields such as enzyme engineering, biotransformation, biosensing, biofuel & energy production, and designing highly biocompatible, non-toxic (Arvidsson *et al*. [4]), and environmentally-friendly nanomaterials and assemblies.

The substances, which can catalyse different chemical reactions in living systems are called biocatalysts. Best examples are enzymes, which are biological compounds (derived from micro- organisms, plants or animal tissue) worked as nature's catalysts and promoted chemical reactions in biological as well as natural systems. Microbial lipases are a class of enzymes, well known as biocatalysts and these are used in a broad range of chemical and biological reactions. These enzymes find numerous applications such as pharmaceuticals, cosmetics, waste water treatments, foods, tanning, detergents, *etc*.

Various enzymes can be used as biocatalysts for different analytical purposes in medical diagnostics and manufacturing purposes in large-scale industrial processes. They have catalytic properties, but their industrial applications are limited due to a lack of long-term stability under process conditions. There is a demand to resolve the difficulties associated with recycling before the enzyme is implemented on an industrial scale. Here, immobilization of enzymes is a novel approach, which can improve half-life, stability, catalytic activity, and reusability of enzymes. Graphene-based nanomaterials are nanoscale and thermo stable inorganic carriers. There are also nontoxic materials and selective modulators for enzyme activity.

APPLICATIONS OF GRAPHENE BASED BIOCATALYSTS

Immobilization of Enzymes

Enzyme immobilization is an interesting field of research and many enzymes are useful in medical fields and food processing industries and this immobilization can improve their activity and stability. Immobilization has certain advantages such as increasing catalytic activity, improvement of stability, easy recovery of enzyme, reuse, *etc*.

A green and efficient Rassi has developed one-pot procedure and Baharfar [1] to achieve indole based amides using Passerini reaction, which involves indole--carboxylic acids, aromatic aldehydes and alkyl isocyanides in the presence of immobilized lipase on graphene oxide. This method has many advantages such as simple operation, mild reaction conditions, good to excellent yields, environmental compatibility and no side products.

The Passerini reaction was performed in the presence of GO@lipase as a green heterogeneous catalyst for the synthesis of indole based a-acyloxycarboxamide derivatives. Activity, efficiency and reusability of *Aspergillus Niger* Lipase (ANL) immobilized on graphene oxide (GO@lipase) were demonstrated. As-prepared nanobiocatalyst was found applicable in multi-component reactions (MCRs) as a heterogenous biocatalyst.

Adeel *et al*. [2] reported that graphene-based nanomaterials had attracted research interest in different fields related to proteins. They have exceptional physiochemical properties such as optical, thermal, electrical, and mechanical strength, so graphene-based nanostructured materials are considered suitable for many applications in varried fields such as electrochemical sensors, electroanalytical chemistry and immobilization of biomolecules and enzymes. Graphene oxide has different functionalities, such as epoxy, hydroxyl, and carboxylic group, which has opened new avenues to modify GO to achieve materials with desired properties.

Ariaeenejad *et al*. [3] reported bifunctional applications of a novel immobilized enzyme on the modified magnetic graphene oxide (GO) for the effective removal of dyes from water. The amine functionalized GO nano-carrier was covalently attached to a model enzyme (PersiManXyn1). It was observed that the specific activities of the free and immobilized enzymes were 856.05 and 1141.1 $\mu molmin^{-1}mg^{-1}$, respectively based an enzyme assays. The free enzyme showed only 5% of its maximum activity, while the immobilized PersiManXyn1 preserved more than 35% of its activity at 90°C. It was revealed that the free enzyme was deactivated after four weeks of storage, but the immobilized enzyme retained 54% of its initial activity. ImmobilizedPersiManXyn1 was applied for the removal of dye from water. The immobilized PersiManXyn1 could catalytically reduce the dye solutions (94% dye removal after 15^{th} cycle), while pristine nano-carrier and free enzyme showed no considerable catalytic ability within 150s. It retained its superior reusability. This immobilized PersiManXyn1 finds its practical applications in the treatment of real textile effluent.

Graphene oxide is a potential candidate for enzyme immobilization, because it has large specific surface area. GO was first functionalized with L-aspartic acid (GO-Asp) by Monajati *et al*. [5]. Then L-asparaginase was immobilized on the GO-Asp either physically or through chemical conjugation. It was reported that a significant enzyme loading could be achieved through covalent immobilization (almost 100% immobilization efficiency). They also examined stability of free and immobilized L-asparaginase in a wide range of temperatures (20–60°C) and pH (5–9). It was revealed that covalently immobilized L-asparaginase exhibited higher enzyme activity than the free enzyme at pH 8, with the maximum

recovered activity of 100, 90.5 and 40.6% after 24h of incubation at 20, 40 and 60°C, respectively. The covalently immobilized L-asparaginase on GO-Asp was found to have 42% recovered activity even after eight continuous reaction cycles at 60°C. It was also indicated that no significant changes were there in the enzyme affinity through covalent conjugation. It was suggested that GO-Asp is suitable as a nanosheet support for L-asparaginase loading and later, it can find some industrial applications in future.

They synthesized a graphene-based matrix for immobilization of L-asparaginase. Asp was used for GO functionalization so that its dispersion and stability could be improved. Here, Asp acts as a spacer between graphene and immobilized enzyme to avoid any extensive structural damage of the enzyme. It was observed that thermal and pH stability of L-asparaginase was improved on immobilization. The covalent attachment of L-asparaginase on GO-Asp was found to retain the enzyme activity more at high temperature and pH 40.6% after 24 h heating at 60°C and pH 8 as compared to physical adsorption (25.1%) and free L-asparaginase (12.9%). It was reported that recovered activity of L-asparaginase retained about 29% and 42% of the initial activity for physically adsorbed and chemically conjugated L-asparaginase after 8 cycles at 60°C.

Dutta *et al*. [6] reported that immobilization conferred psychrostability to a cold active α-amylase (amy) enzyme using magnesium nanoparticle (Mg NP) and graphene oxide. It was revealed that GO-Mg NP-amy nanocomposite showed enhanced enzymatic activity and thermo stability at both; the temperature extremes; upper (90°C) and lower (8°C). The GO-Mg NP-amy exhibited increased affinity towards the substrate, which is reflected in the decline in its Km by 2.35 and 14.9-fold at 8° and 90°C, respectively, as-compared to untreated enzyme. They also found that GO-Mg NP-amy showed 2.34-fold and 4.29-fold increase in Vmax at 8° and 90°C, respectively, compared to the untreated enzyme. The half life of GO-Mg NP-amy was increased by 44-fold with simultaneous increase in E_d by 1.9-fold as compared to the native enzyme at 90°C. The same is true for8°C, half-life of GO-Mg NP-amy increased by 6.48-fold with the simultaneous increase in E_d by 2.21-fold as compared to the native enzyme. It was observed that enzymatic activity of GO-Mg NP-amy was retained even after 12 consecutive uses and had storage stability for more than 120 days at 4°C. The ability of GO-Mg NP to sustain and aggravate enzyme activity and stability at temperatures in a wide range can make it a better candidate in bioprocessing industries, which requires functioning at these extreme ranges of temperature.

Gür *et al*. [7] prepared graphene oxide and reduced graphene oxide (rGO) Langmuir-Blodgett (LB) films with specific surface properties and functional groups as negative ideal substrates. They immobilized polyphenol oxidase (PPO)

enzyme on these films by electrostatic interaction without any requirement of chemical bonding or surface modification. It was reported that catalytic performances of the enzyme immobilized on GO and rGO substrates were higher in GO-PPO LB films as compared to rGO-PPO LB films *in-vitro* media. It was revealed that the immobilized PPO enzyme on biodegradable GO was superior to the inorganic materials in terms of its use in biological systems. They prepared regular film structures with a single molecule thickness by LB film technique, which contributed to the stability and recycling of immobilization of PPO enzyme on GO and rGO. It was found that *in-vitro* storage stability of immobilization on both film structures was about one month at +4°C.

Li *et al*. [8] prepared three-dimensional magnetic graphene oxide-magnetite polyvinyl alcohol (3D-GO/PVA/Fe_3O_4) nanocomposites. It was reported that the specific surface and the average pore size of 3D-GO/PVA/Fe_3O_4 nanocomposites were 388.87 m^2g^{-1} and 9.6nm, respectively. The higher specific surface indicated that the three-dimensional structure avoided any aggregation for GO sheets. The saturation magnetization (Ms) of the nanocomposites was found to be large (30.5 $emug^{-1}$), which enabled the easy cycling of such nanocomposites. It was revealed that 3D-GO/PVA/Fe_3O_4 nanocomposites exhibited better performance for porcine pancreatic lipase (PPL) enzyme immobilization and it could reach the efficiency of 91%, and the enzyme immobilized nanocomposites reached up to 90% of their activities. It was observed that the activity of the immobilized enzyme retained 70.8% of its initial activity after 10 cycles. The activity of the immobilized enzyme remained up to 71.1% at 4°C for 56 days. Hydroxyl-rich PVA provided more binding sites for immobilizing enzyme and best-immobilized efficiency for (3D-GO/PVA/Fe_3O_4)-PPL (91%) was much more as compared to (GO/Fe_3O_4)-PPL (76%).

Immobilization of lipase was successfully achieved by Heidarizadeh *et al*. [9] on the surface of magnetically separable Fe_3O_4/graphene oxide through a post-modification. This modification was achieved in alternation to glutar aldehyde post-modification. It was revealed that the activity of immobilized lipase had no significant loss in the activity, and it can be simply separated (by keeping its major activity) from reaction crude using a magnet.

Dithiocarbamate can modify magnetic graphene oxide nanocomposite (Fe_3O_4-GO) for immobilization of covalent enzyme (lipase).Fabricated Fe_3O_4/GO-NHCS-Lip acts as a nanobiocatalyst for enzymatic hydrolysis of PNPD. It was reported that the recyclability of immobilized lipase is due to the fact that it is covalently attached to the surface and the leaching issue was not observed in this protocol.

The synthesis, characterization and biological application of reduced graphene oxide–chitosan (GC) based benign supramolecular scaffold (SMS) has been reported by Mondal *et al*. [10]. It was observed that immobilization of polyphenol oxidase (PPO) onto GC lowers the Michaelis-Menten constant (Km) value, which helps in achieving maximum velocity at lower substrate concentrations. In corporation of gold nanoparticles in GC (GCG) further strengthens the microbial resistance properties of GC and also improves its biocompatibility by reducing cytotoxicity.

A new rGO-chitosan (GC) based supramolecular scaffold (SMS) has desired thickness (55 nm), surface morphology and functionality for immobilization of enzyme and AuNP implantation. Its bio fabrication properties revealed that-

- Synthesized GC serves as an excellent enzyme (PPO) immobilizing matrix with low Km value and hence, a lesser amount of substrate is required to achieve maximum velocity,
- GC and GCG both possess antibacterial and antifungal activity and the presence of Au NP in GC (GCG) improved this antimicrobial activity as compared to GC alone,
- Biocompatibility study (MTT assay) on macrophage culture indicated that 91 and 98% cells are viable for GC and GCG, respectively and therefore, both the composite possesses no noticeable adverse effect on the cells and,
- It was also found that as-synthesized materials are suitable for *in vitro* cell growth.

Hence, these environmentally benign and biocompatible materials can be used in industries for the removal of phenolic, food packaging, biomedical coating and tissue engineering.

Magnetic graphene oxide (GO-MNP) was synthesized by Paz-Cedeno *et al*. [11] and used as the immobilization support for an industrial cellulase- and xylanase-containing preparation. The enzymatic preparation was immobilized utilizing carbodiimide cross-linking chemistry using 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide and *N*-hydroxysuccinimide (NHS). It was revealed that the supported final biocatalyst (GO-MNP-Enz) exhibited higher activity for the hydrolysis of pretreated sugarcane bagasse (PSB). It presented relative β-glucosidase, endoglucanase, β-xylosidase and xylanase activities of 70, 66, 88, and 70%, respectively, after 10 cycles of hydrolysis of their respective substrates. It was also revealed that biocatalyst also maintained approximately 50 and 80% of its efficiency for cellulose and xylan hydrolysis, respectively. It was suggested that GO-MNP-Enz may be a prospective candidate for industrial applications such as second-generation ethanol production.

The yield, efficiency, and relative activity of the immobilization process ranked from 27–97, 37–113, and 24–110%, respectively, for the different enzymatic activities assessed. It was observed that cellulose conversion to glucose was diminished in comparison to the initial cycles, when GO-MNP-Enz was used multiple times in the hydrolysis of PSB, where xylan conversion to xylose remained high and stable at levels greater than 60% up to the tenth cycle. It was proposed that the use of GO-MNP-Enz is a cost-effective strategy for more competitive hydrolysis of PSB, and it has a potential for application in the production of second-generation ethanol, where the cost of enzymes is considered the bottleneck that prevents its economic viability.

Ameri *et al*. [12] immobilized thermo alkalophilic lipase from *Bacillus atrophaeus* (*Ba*L) onto amine-functionalized graphene oxide nanosheets, which were coated with the poly(maleic anhydride-alt-1-octadecene) copolymer (GO-NH_2-PMAO) and activated with glutaraldehyde as spacer arm through interfacial activation and subsequent multipoint covalent attachment. Immobilization conditions were optimized, such as GO-NH_2- concentration of PMAO, buffer & enzyme glutaraldehyde concentration, pH, time of sonication, concentration, time, and temperature. It was reported that specific activity of the immobilized *Ba*L (105.95 ± 2.37 Umg^{-1}) reached at 5 mg mL^{-1} for GO-NH_2-PMAO, 25 mM of buffer, pH 6.0, 60 min sonication time, 100 mM glutaraldehyde, 60 U mL^{-1} of the enzyme, and 4 h of immobilization time at 25°C, and it was very close to the predicted amount (106.08 ± 1.42 U mg^{-1}). Maximum immobilization yield and efficiency were found to be 81.35 and 277.63% in optimal immobilization conditions. It was indicated that the immobilized *Ba*L showed better stability at extreme temperature and pH than the free *Ba*L and it could retain more than 90% of the initial activity at a temperature of 90°C and pH 11 even after 10 days of storage and 6 cycles of application. It was revealed that maximum bioconversion of valeric acid to pentyl valerate was there in the xylene medium after 48 h of incubation at 60°C using the free *Ba*L (34.5%) and the immobilized *Ba*L (96.3%). This, *Ba*L immobilized on GO-NH_2-PMAO can be used as an effective biocatalyst to synthesize ester with the flavour of green apple.

Asmat *et al*. [13] treated *Candida rugosa* lipase (CRL) with surfactants and immobilized it onto the novel formulated magnetic graphene anchored silica nanocomposite (Fe_3O_4/SiO_2/Gr NC). The surface of lipase was initially coated with Triton-X 100 and cetyltrimethylammonium bromide (CTAB) surfactants to stabilize the enzyme in its open form and it was then adsorbed onto aminated Fe_3O_4/SiO_2/Gr NC. Here, glutaraldehyde (GA) was used to cross-link the adsorbed lipase onto the NC. It was reported that surfactant stabilized immobilized lipase exhibited significantly enhanced thermo stability, and also tolerance to various metal ions and inhibitors. The immobilization yield was remarkably enhanced by

6-folds and 3-folds using Triton X-100 and CTAB, respectively. As-fabricated nanobiocatalysts were used to synthesise green apple flavour ester, ethyl valerate *via* esterification reaction. It was found that Triton X-100 stabilized immobilized lipase performed better, giving about 90% ester yield as compared to 78% yield obtained with CTAB stabilized immobilized lipase.

A simple and effective method for lipase immobilization onto nanocellulose fused Ppy functionalized GO composite was developed by Asmat and Husain [14]. As-prepared nanobioconjugate exhibited significant catalytic performance, stability and solvent tolerance. This is an easy method of preparation and high stability nanobiocatalyst CRL@ Ppy/NCe/GO CRL immobilized on Ppy/NCe/GO, which exhibited enhanced catalytic performance and 160% of activity yield percentage was obtained. It was reported that immobilized lipase formulation (nanobiocatalyst) retained 85% of its original catalytic activity even after 10 cycles of application. It was employed for the synthesis of ethyl acetoacetate. The use of immobilized lipase gave flavour compounds with 27.5 and 75.5% ester yields in solvent-free media and n-hexane, respectively.

Jafarian *et al*. [15] synthesised graphene oxide nanosheets (GON) and its functionalization with 2, 4, 6-trichloro-1, 3, 5-triazine (TCT) through two different routes:

- Directly reaction of GON with TCT (GON-1), and
- Reaction of GON with pre-functionalized TCT with 3-aminopropyl-triethoxysilane (APTS) (GON-2).

Then GON, GON-1 and GON-2 were used as supports for immobilization of *Candida rugosa* lipase (CRL). The values of loading capacity, immobilization yield and leaching of CRL were found in the following order:

GON>GON-1>GON-2

But this order is reversed for a specific activity and recovered activity. It was found that storage stability was high with reasonable reusability for all the immobilized CRL, while the pH and thermal stability of CRL@GON-2 were higher than the remaining two. The advantages of these supports include biocompatibility, low toxicity, high enzyme stability, low cost production, convenient separation of the supports from the solution and relatively high reusability of the enzyme, which make them promising candidates for practical applications.

Kashefi *et al*. [16] synthesized graphene oxide by modified Hummer's method and used it as an ideal enzyme immobilization support because of its specific chemical and structural features. Then they covalently immobilized laccase from genetically modified Aspergillusonto GO (nanobiocatalyst). It exhibited interesting results such as laccase loading (156.5mgg^{-1}) and immobilization yield (64.6%) at laccase concentration (0.9mgmL^{-1}). Bioconversion of two anionic dyes; Direct red 23 (DR23) and acid blue 92 (AB92) was studied using nanobiocatalyst and optimized. It was found that average decolorization effectiveness of the nanobiocatalyst was more than 75% for both these dyes after six cycles, which indicated its excellent operational stability and good reusability.

Gao *et al*. [17] fabricated and characterized glucose oxidase (GOx) and chloroperoxidase (CPO) on the surface of MGO. The performance of as-synthesized immobilized CPO was enhanced by coupling with GOx providing required H_2O_2*in situ* through oxidation of glucose. The activity of MGO-GO--CPO for the decolorization of orange G was much higher (96.6%) than MGO-GOx+MGO-CPO (86.2%). It may be due to reduced mass transfer resistance between CPO and H_2O_2 generated from GOx molecules. It was found that MGO-GOx-CPO reached its highest activity (95.2%) in the temperature range 42-50°C as compared to 35°C for the free enzyme. It was attributed to dispersion of the otherwise stacked MGO below 42°C. This can be conveniently reused as it can be easily recovered in the presence of an external magnetic field, and retained ~38.5% activity even after 6 cycles of applications. Thus, as-synthesized MGO-GOx-CPO has potential applications in the environmental field.

Xylanaseenzyme was immobilized by Mehnati-Najafabadi*et al* [18]. on superparamagnetic garphene oxide nanosheets (GOMNP). It is a hydrolytic enzyme of xylan, which is widely used in industry. Asxylan is bulk, polyethylene glycol bisamine (PEGA) and, it was used as a spacer for functionalization of GOMNP to enhance the accessibility of active sites of the immobilized xylanase. It was reported that xylanase was attached to the functionalized nanocomposite with a yield of 273 mg enzyme g^{-1} PEGA-GOMNP. It was found that free and immobilized xylanase displayed an optimal enzymatic activity and pH 6.5 and 7.5, respectively, at 60°C. The immobilized enzyme retained about 40% of its initial activity even after 8 cycles. It was observed that immobilized and free enzymes retained 35 and 20% of initial catalytic activity after 90 days storage at 4 °C, respectively. The PEGA- modified GOMNP can be used as biodegradable and suitable support for bioengineering.

Desai *et al*. [19] immobilizedamylase on graphene oxide (GO)–magnetite (Fe_3O_4) nanoparticles through covalent bonding. Different operating parameters were optimized as concentrations of GO (1.3 mg), Fe_3O_4 (58 µg), and amylase (4.5 mg).

High loading capacity of 77.58 μg amylase over 1 μg GO-magnetite nanoparticles could be achieved under optimum conditions. The optimum pH remained the same (7), but alkalitolerance was increased by ~20% in relative activities upon immobilization. It was observed that half-life of soluble amylase was found to be 13 h, which was enhanced to 20 h upon immobilization in 20 mM phosphate buffer, pH 7 at 50°C. The immobilized amylase could be used for 11 consecutive runs.

Pectinase was immobilized by Dai *et al*. [20] onto sodium alginate/graphene oxide beads *via* amide bonds. They used *N*,*N*′-dicyclohexylcarbodiimide/*N*-hydroxysuccinimide as the activating agent. The activity of the as-prepared immobilized pectinase (1236.86±40.21 U g^{-1}) at optimal conditions had enzyme activity recovery 83.5%. The optimal pH of free pectinase was 4.5, which was shifted to 4.0 in the case of immobilized pectinase. The optimal temperature of immobilized pectinase was also increased by 10°C (60°C) as compared to the free form (50°C). It was observed that the immobilized pectinase had a superior thermal and storage stability than that of free pectinase. It was indicated that immobilized pectinase retained 73% of initial activity even after six cycles. Such immobilized pectinase may find various applications in the food industry.

Bifunctional acid urease is useful in reducing harmful substances in rice wine and it also effectively removes ethyl carbamate (EC). The acid urease was immobilized by Yang *et al*. [21] on graphene oxide/chitosan beads. It was observed that immobilized urease can be recovered to 77% from the graphene oxide/chitosan composite when it was coupled for 8 h with 5% glutaraldehyde. The optimum temperature for urease activity was found to be 37°C. The stability of the immobilized urease was improved at 37°C and the half-life of decay in urease activity was only 12 h, whereas it was 43 days for soluble and chitosan/graphene oxide immobilized urease at 4°C. The Km value for urea and EC in the free state was 9.14 mM and 386 mM, respectively, which were 5.28 mM and 180 mM, respectively, relatively lower in the immobilized state. The values of Vmax for immobilized EC and urea were observed to be 1.08 and 1.16 μmol min^{-1}, respectively, which were higher for soluble EC and urea 0.782 and 0.931 μmol min^{-1}, respectively. Furthermore, 90% of the initial activity of graphene oxide/chitosan–urease beads was retained after using the beads 10 times; thus, indicating its excellent reusability.

Dutta *et al*. purified an extracellular phytase from a strain of *Bacillus subtilis* obtained from cattle sheds in 24 Parganas (Kolkata, West Bengal) by Dutta *et al*. [22]. The native enzyme showed optimum activity at 42°C and pH 8.5. but it showed 2.40 fold increased activity at 42°C and more than 20-fold activity increment at 85°C in the presence of magnesium nanoparticle (Mg NP) graphene

oxide immobilized enzyme, respectively. The GO-Mg NP-phy complex (phytase coupled to Mg NP immobilized on graphene oxide) had a decrease in Km by 3.29 folds at 42°C and 6 folds at 85°C, and the enzyme system showed 3 fold and 5.5 fold increase in Vmax at 42°C and 85°C, respectively than the untreated enzyme. The energy of activation (Ea) was also lowered by 2.5 and 6 folds, respectively at 42°C and 85°C for GO-MgN-phy as compared to the untreated enzyme. The half life for GO-Mg NP-phy was found to be 29.5 times of that of the untreated enzyme. It was reported that enzymatic activity of GO-Mg NP-phy was retained by 86.6%, when it was tested for storage stability at 4°C after 140 days. This immobilization technique may be used in developing a thermostable phytase enzyme,which could withstand high temperatures during the pelleting of animal feeds and increased activity of the enzyme would also be beneficial to break down phytic acid during storage of feeds.

Different kinds of amino acids were used by Zhuang *et al*. [23] to reduce and modify GO. It was found that reduction and adsorption disparities of amino acids were responsible for the difference of structural heterogeneity such as density, thermal tolerance and disorder of the oxygen-containing groups of GO. This modification also resulted in changes in surface properties of the GO samples, such as hydrophobicity and surface charge. They functionalized GO as a carrier for the immobilization of lipase from *Thermomyces lanuginosus* (lipase TL). It was found that lipase immobilized on functionalized GO exhibited superior enzymatic loading and relative activity compared to GO, with a maximum increase of 70 and 47%, respectively. The relative activity of lipase immobilized on functionalized GO was reported to be 19.21 times more than commercial immobilized lipase TLIM.

Zhuang *et al*. [24] also used disodium guanosine 5′-monophosphate (GMP-2Na) as a reducing agent for the synthesis of functionalized GO (FGO) for lipase immobilization. This method could solve the toxic and hazardous issues of the agents in the chemical reduction process of graphene oxide.The degree of hydrophobicity of FGO was conducive to the formation of optimal conformation of lipase, when the concentration of GMP-2Na is 0.20mg mL^{-1}.The activity of the immobilized enzyme was enhanced by two folds of free enzyme after immobilization. Here, the protein loading reached 600mg g^{-1}. The immobilized enzyme has much durability as no significant decrease was observed after incubation for 8h at pH6.0 and 7.0. The activity of the GO-G@ enzyme was found to be 54.47% higher than that of free enzyme after storage for 35days.
